Weight in ounces. + = death.

Finally, with regard to the eight fatal cases of the tabulated series, in one case only (No. 14) was evidence obtained of a secondary streptococcal invasion. Heart bloods post mortem were usually sterile. From spleens, livers, and lungs only occasional contaminants, mainly of coliform or gelatin-liquefying types, were recovered. The freedom from secondary bacterial invasions exhibited by these early fatal cases gave the necessary confidence in interpreting the histological features of the visceral lesions. To this subject we now come.

Histology of the Visceral Lesions.

The histological features of visceral lesions following the introduction of neurotesticular vaccine by intravenous and intradermal routes have been studied so far in 22 rabbits—viz., (A) 8 fatal cases at six to twelve days after intravenous inoculation (see Table); (B) 4 rabbits similarly inoculated, but sacrificed between the sixth and sixteenth day; (C) 3 rabbits, *R. 70*, *R. 81*, *R. 73*, intradermally inoculated and showing some evidence of generalisation at death on twentieth, twenty-fifth and sixtieth days; (D) 5 rabbits intradermally inoculated and sacrificed on fourth, sixth, sixteenth, twenty-first, and twenty-first days, *R. 93*, *R. 85*, *R. 65*, *R. 69*, *R. 70*; and (E) 2 rabbits sacrificed five months after an intravenous inoculation from which they did not appear to suffer. In addition, suspicious spots in organs of animals inoculated with various bacteria (pasteurella, anthracoid organisms, pneumococcus, &c.) have been examined for comparative purposes. It is proposed here to record the main features only, pending a fuller illustrated study to be published later.

Series A.—The most satisfactory material has been that obtained from the early fatal cases (see Table) in which there was no evidence that death was due to other causes than the virus. The four surviving animals of this series are being retained for study of possible late lesions.

Liver.—Multiple focal necroses of liver cells, showing, as a rule, evidence of initial hæmorrhage, is the prevailing lesion. These necroses are precisely similar to those met with in certain acute bacterial infections—e.g., spontaneous rat plague—and need no description. In those rabbits which died at the later periods (9–12 days) there was evidence of rapid replacement of necrotic areas by bile-duct proliferation.

Lung.—The feature here also is the presence of discrete or confluent areas of necroses of alveolar tissue accompanied by hæmorrhage. In the worst cases little healthy alveolar tissue may be left. Walls of blood-vessels and bronchi are severely involved in the general necroses and there is little or no attempt at delimitation of the lesions by proliferation of adventitial cells of vascular sheaths. Where a hæmorrhagic necrotic focus is situated in the subpleural region, as frequently happens, a striking defence mechanism is afforded by the formation of a lens-shaped hyperplasia of the overlying serous endothelium. This structure is responsible for the raised macroscopic foci on the lung surface.

Ovary.—Lesions, when present, took the form of acute hæmorrhagic necroses, sometimes very extensive, in the interstitial tissue of the organ. There was no evidence of repair.

Spleen.—Isolated focal necroses in the pulp were noted in one case only.

Brain.—The animals had shown no symptoms pointing to cerebral disturbance during life. In three of the fatal cases, however, the brain was examined microscopically and showed no obvious lesions.

Adrenal.—In all the fatal cases of the series this organ presented focal necroses, discrete or confluent. As many as 25 discrete necroses have been counted in a cross section, so that the amount of functioning cortical tissue is greatly curtailed. The necroses are most commonly found in the mid cortex, but in two cases they have been noted in the medulla. The destruction of the adrenal cells is accompanied in the early stages by hæmorrhage, and considerable congestion of vessels is seen at the periphery of the lesion. In one case only (No. 10) which was the last to succumb (on the twelfth day) was there evidence of reaction on the part of the local reticulo-endothelial tissue. In this case the single large necrotic focus present was surrounded by a narrow zone of adventitial cells of plasmacytoid type.

Pocks on Skin of Back.—As noted above these lesions took the form of purpuric foci accompanied by œdema of the dermal tissue. Section of these areas showed massive necrosis with hæmorrhage of all vascular tissues in dermis down to the skin muscle, the bundles of which were also degenerate. There was no trace of repair.

Series B.—Of the four animals of this series (all older animals and weighing about 5 lb.) two were killed on the sixth and seventh days respectively, while apparently unaffected clinically by the intravenous dose, and the other two on the thirteenth and sixteenth days.

In one of the two former there were no necroses in liver, spleen, or adrenal, and only one fairly large focus in the lung section. Here, however, it was noted that the reticulo-endothelial tissue in the neighbourhood of the larger vessels and bronchi showed very marked proliferation, and that polynuclear cells were infiltrating the necrotic area. In the other animal the lungs contained numerous confluent necroses, but there was very definite reaction on the part of the vessel sheaths. These proliferated sheaths are striking objects in all vessels not completely necrosed. The liver also showed foci containing proliferated bile-duct epithelium, apparently replacing areas of initial necroses. Uterus and ovaries contained widespread hæmorrhagic necroses, but even at this early stage defence processes were in evidence. Ovarian and uterine necroses showed vast numbers of infiltrating polynuclears which were usually absent in the necroses of the early fatal cases, and there were numerous wandering macrophages with included polynuclears. Collections of the latter cells with their nuclei fused together in horseshoe form, and their granules massed in the centre simulated in a remarkable way the Langhans giant-cell. When the necroses underlay the serosa, the serosal endothelium was proliferated to form a dome of many layers.

The adrenal section presented four large necroses with many infiltrating polynuclears, but no ring of new reticulo-endothelial tissue. This case also was the only one of the series in which grey papules were present on the serosa of the bowel wall. The necrotic lesion here was confined to the serous coat and underlying tissue. The muscular coats were not penetrated. At the surface the serous endothelium showed great hyperplasia with many mitoses.

Of the two killed on the thirteenth and sixteenth days, one only presented both in lung and adrenal isolated necroses surrounded by proliferated adventitial and plasmacytoid cells.

Series C and D (with exception of *R. 85* and *R. 93*).—The lesions met with in these animals, particularly those affecting the liver, were at times difficult to interpret.

Only *R. 70* and *R. 81* presented necroses in the lungs. In *R. 70*, which was killed on the tw[illegible] day, the single large necrosis noted in the lung s[illegible] surrounded by proliferated reticulo-endothelial [illegible] there was evidenc[illegible]ation of new alv[illegible] In *R. 81*, whic[illegible]d to a pneumoco[illegible], the lung show[illegible] and many [illegible] infiltrating the [illegible], but no ret[illegible]sponse.

In *R. 70*, *R. 81*, and *R. 73*, the adrenals presented necroses, usually single, and surrounded by massive development of reticulo-endothelial cells.

R. 76, *R. 70*, and *R. 81* presented massive necroses in the walls of uterine horns extending to the mucosa, but there was already an attempt to delimit these areas by new reticulo-endothelial tissue. The small spot on the uterus of *R. 73* proved to be a granulomatous nodule of undetermined nature, attached to the serosa.

The scattered pearly spots observed on and in the livers of certain animals of this series and which, to the naked eye, corresponded tolerably well with those in the acute fatal cases, though fewer in number and of somewhat larger size, proved on section to be granulomatous areas with dense fibrous walls infiltrated with eosinophil cells. Occasionally enormous syncytial giant cells with many nuclei were present, and not infrequently a necrotic mass was present in the centre of the granuloma. We have come to the conclusion that all these spots represent some phase or other of the strange granulomatous foci known to be associated with coccidiosis, and that they have no relation to any antecedent vaccinial infection.

There is collateral evidence in support of this view. *R. 85*, which was killed on the sixth day after intradermal inoculation, presented similar granulomata in the liver with walls infiltrated by eosins. The adrenal section showed five necrotic foci round one of which there was already a new ring of reticulo-endothelial tissue. This case is of interest in that it demonstrates visceral generalisation so early as the sixth day after intradermal inoculation. Also in No. 16 (see Table), in addition to the multiple acute necroses in the liver, there were older areas containing *Eimeria stiedæ*.

The spots on the liver of *R. 93*, killed four days after inoculation intradermally with pure dermal virus, which is not known in our experience to have the property of generalising, were examined and found to consist of granulomatous masses containing remarkable giant-cell formations. Interlobular cirrhosis was present in the liver of this animal and in the livers of certain other animals of this series.

Finally, with regard to the two animals of *Series E*, which were sacrificed 148 and 165 days after an intravenous injection of neurotesticular vaccine, one of them showed an adrenal necrotic focus with massive development of new reticulo-endothelial tissue at its periphery. The giant-cell granulomata found in its liver were probably of coccidial origin. The other animal presented no lesions in liver or adrenal, but in the lung there were areas of massive perivascular infiltration containing occasionally giant cells of the fused nuclear type. No remains of initial necroses were seen, but the distribution of these areas might reasonably suggest a late stage in the healing of initial necroses. They appear to be identical with those figured by McIntosh and Scarff (1929) in a recent paper.

To conclude this section, it may be noted that spots simulating (to the naked eye) those met with in *Series C* and *D* have been found in the livers of animals inoculated with various bacteria. They cannot, however, be attributed to these experimental infections. For example, in animals inoculated intravenously with large doses of *P. lepiseptica* granulomatous areas have been present in the livers alongside the characteristic focal necroses due to the bacterial infection.

Discussion.

The observations we have recorded in this communication are in substantial agreement with those of Douglas, Smith, and Price, of McIntosh and Scarff (1929), and of Bijl and Frenkel (1929), whose paper dealing with the histology of visceral lesions following cutaneous vaccination of rabbits with neurovaccine appeared while these notes were being written. The suggestion for which one of us (L.) was responsible, that pasteurellar or other latent infection in rabbits might become active in response to the virus invasion and account for the lung and liver lesions has not been supported by the data here adduced. It is clear that the vaccine virus in the form of neurovaccine or neurotesticular vaccine is capable, in whatever site introduced, of doing what cutaneous strains of virus are capable of doing only when introduced into the blood stream (picture of Camus). The "organ" virus has the further property of producing macroscopic lesions in many viscera.

It is remarkable that our present knowledge of the generalising properties of vaccinia has been reached so gradually. Camus attributed his successful results with cutaneous vaccine intravenously introduced to adequate dosage, and this factor is also of importance with neurovaccine. Young animals also would appear to be more responsive, as Douglas, Smith, and Price assert. Consideration of the histological features of lesions following neurovaccine does not suggest that the virus by passage through testis or brain or both has acquired new properties, but rather that it has become possessed in intensified form of properties shared also in a limited degree by strains of cutaneous source. The latter, when introduced into the dermis, will invariably produce some degree of necrotising action on vascular endothelium and reticulo-endothelial tissues generally, with consequent hæmorrhage. Introduction of neurovaccine into the dermis is followed on the other hand by widespread destruction of vascular tissue and widespread hæmorrhage. The diffusive uncircumscribed character of the skin reaction following intradermal inoculation of neurovaccine, with its peculiar purplish-black tint, is due to this, as histological examination shows. Increased endotheliotoxic or endotheliolytic powers, therefore, must increase not only the chance of invasion from a skin area, but also the strength of that invasion, and it is on the latter presumably that the production of actual visceral lesions will depend.

Reynals (1928) has shown that the addition of certain tissue extracts—(e.g., renal or testicular) to cutaneous strains of virus will very markedly enhance the dermal response following intradermal inoculation, thus rendering it very similar to that produced by neurovaccine. As neurotesticular vaccine can produce its characteristic skin reaction when employed in very high dilution, the "Reynals" factor is likely to account, only in a minor degree, for the enhanced virulence exhibited by strains which have been repeatedly passed through organs. That by repeated passage through a particular tissue a virus may acquire an increased power of proliferation in that tissue, and at the same time lose much of its power of propagation on the tissue on which it was originally propagated (scarified skin surface) has been shown by Ledingham and McClean (1928) in the case of virus propagated from dermis to dermis. This dermal virus, however, has never shown signs of generalisation either in skin or organs when implanted in a dermal area. Further research must elucidate the mechanism of these adaptations.

In the meantime it seems clear on general grounds that neurovaccine, while not apparently neurotropic, has nothing to recommend it as a form of vaccine lymph for human use. Bijl and Frenkel (loc. cit.) state that neurovaccine, which has been employed to some extent in Holland, involves a greater risk of postvaccinal encephalitis. So far, we have not seen the Dutch statistics on which this important assertion is based. It is freely stated, however, that the neurovaccine is liable to produce rather severe local reactions and to be followed not infrequently by generalised vaccinia. On the other hand, as Bijl and Frenkel remark, postvaccinal encephalitis is not known to be accompanied by generalised vaccinia in any form. Indeed, in the great majority of cases the vaccinations (with calf lymph) have run a normal course. There is the further fact that so far as our present knowledge goes, the brain is not involved in the generalised lesion syndrome (as distinct from simple virus invasion) following the introduction of neurovaccine in rabbits. Moreover, when neurovaccine is introduced directly into the brain of the rabbit, meningitis but not encephalitis is produced.

Huon and Placidi (1921) some years ago reported the occurrence of cerebral and paralytic symptoms in rabbits inoculated with a particular strain of lymph which had been propagated on asses. Death in coma was liable to occur on the fourth or fifth day, and vaccinal pustules were present on the tongue and buccal mucosa. A sample of this lymph, which had been kept in cold storage for some time, was kindly forwarded to one of us (L.) by M. Huon, of Marseilles, and tested on rabbits in London. The rabbits reacted normally to the virus, and there was no evidence whatever of cerebral disturbance.

Owing to its liability to spontaneous forms of encephalitis the rabbit has not proved a very suitable experimental animal for the investigation of problems concerned with the possible implication of the central nervous system in the syndrome that may follow the introduction into the skin of any form of vaccine virus. Though activation of latent bacterial infection has played no part in the production of the visceral lesions following introduction of neurovaccine, it is not to be assumed that such activation is a negligible contingency. The above-cited experience of Pette and many collateral data concerned with bacterial activations in the course of experimental avitaminoses show that the seasonal factor, as well as the degree of incidence of latent infection, are of importance. Moreover, there appears to be no doubt that for the occasional late deaths of rabbits following intradermal inoculation of neurovaccine secondary bacterial infections may be immediately responsible.

With regard, finally, to the visceral lesions and their histological features, perhaps the most interesting are those affecting the adrenals. For the early fatalities described in this paper the severe lung lesions and the widespread hæmorrhages were probably mainly responsible, but the equally severe necrotic lesions present in the adrenals suggest new clinical problems which it may be possible to attack experimentally. We have shown here that after five months such lesions may be demonstrable in process of repair. The experience of Douglas and his colleagues in connexion with pregnant female rabbits and the severity of the uterine lesions in such cases we fully confirm. As to the liver lesions, the vaccinial origin of the multiple focal necroses is not in dispute, but the greatest caution must be exercised in assigning a vaccinial origin to liver spots met with in animals sacrificed at later stages, though these may simulate in a remarkable way the naked-eye appearance of the acute necroses. It is probable that the true initial focal necroses in the rabbit liver become very rapidly replaced by new liver tissue in animals that are to survive.

Brief Summary.

(1) The observations of Douglas, Smith, and Price on the occurrence in rabbits of visceral lesions following the introduction of neurotesticular vaccine are confirmed. (2) These lesions are due to the virus and not to any latent bacterial infection activated by the virus. (3) Some account is given of the histological features of the visceral lesions, and attention is drawn to errors of interpretation that may arise in connexion with liver lesions of other than vaccinial origin. (4) Though not responsible for the visceral lesions, bacterial infections may intervene in the course of the cachexia produced by the virus, and may be responsible for a fatal issue. (5) The bearing of the new knowledge on some current problems is discussed.

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

THE following table brings out some remarkable contrasts in the 1928 statistics of three of our largest cities:—

Name of district and estimated (R.-G.) population.	Birth-rate.	Death-rates per 1000 of the population.					Death-rates per 1000 births.		
		All causes.	Tuberculosis.	Cancer.	Respiratory diseases with influenza.	Heart disease.	Infant and neonatal mortality.	Young child (1–5 yr.) mortality.	†Maternal mortality from childbirth.
Glasgow .. (1,060,500)	22·3*	11·8*	1·22	1·35	2·7	1·9	107/39	61	8·3
Birmingham . (968,000)	18·1	10·9	1·00	1·36	1·7	1·8	65/30	25	3·8
Liverpool .. (866,000)	22·1	13·2	1·38	1·27	3·0	1·0	94/32	54	3·4

* According to the local estimate of the population the Glasgow birth-rate is 20·6 and the death-rate 13·7.

† The death-rates from puerperal sepsis alone were: Glasgow, 3·8; Birmingham, 1·9; Liverpool, 1·0; *and the proportion of* stillbirths to live births: Glasgow, 4·4 per cent.; Birmingham, 3·4 per cent.; Liverpool, 4·0 per cent.

Glasgow.

In this report Dr. A. S. M. Macgregor devotes special attention to the housing problem. The number of houses completed during the year ended August 31st was the highest for half a century—namely, 6885—and included 132 of two rooms, 4184 of three rooms, and 2238 of four rooms. There has also been much building beyond the city boundary. These operations, combined with slum clearance and rehousing, are causing a salutary redistribution of the population. In certain areas there are slight signs of a diminution of overcrowding, but a large volume of overcrowding is due to the occupancy of small houses by large families. The crux of the problem is the provision of houses within the competence of small wage-earners. The report of the supervising nurse-inspector, whose duty it is to visit the families transported from the slums to new houses, shows the extreme difficulty of her task. An effort has recently been made to provide a cheaper house, this type being known in Glasgow as the "intermediate house." In January, 1928, 972 three-roomed and 258 four-roomed houses of this type were available at weekly rentals of 12*s.* 0*d.* and 14*s.* respectively, inclusive of rates, and the corporation decided to let them to overcrowded families with a maximum income of £4 per week, but preferably with less. The director of housing is at an early date to submit the design of a three-roomed house to be let at 10*s.*, and Dr. Macgregor hopes this cheaper "intermediate" house will soon be available for families whose incomes are less than £3 per week, but whose needs are no less clamant than those with higher incomes. The Glasgow Corporation thought they had obtained power to restrict the rentals of farmed-out houses, but a legal decision has shown that it will be necessary to insert a special clause with this object in the next provisional order promoted by the corporation.

The first recorded outbreak of poliomyelitis in Glasgow occurred in 1928. The acute cases coming to the knowledge of the health department numbered 112 and there was usually a long delay between the date of sickening and the official discovery of the case, until the existence of the epidemic had been made known to the medical profession. During the first five months only 10 cases sickened; during June, 5; July, 16; August, 25; September, 28; October, 22; November, 5; and December 1. There was a tendency to grouping in areas, a feature noted in the Glasgow encephalitis outbreak of 1924. The disease showed no predilection for any social class; there were 58 males and 42 females affected; 82 cases occurred under 5 years, 18 from 5 to 10 years, 4 from 10 to 15 years, and 8 were over the age of 15. In two instances cases were associated—two infants living in the same tenement building sickened on July 28th and August 1st respectively, and there was a group of six cases in the junior classes of a day school. There was no evidence of abortive cases, but Dr. Macgregor points out that such evidence is much more difficult to obtain in a town than in a rural area. In 79 per cent. of the cases paralysis appeared within seven days of onset; eight cases ended fatally—four on the third day, three on the fourth day, and one on the fifth day of illness. As regards the relation of these nervous diseases to influenza Dr. Macgregor shows the relationship of encephalitis epidemics to previous influenza epidemics, and points out that the influenza epidemic of January to February, 1929, was preceded by this poliomyelitis outbreak and associated with a concurrent outbreak of cerebro-spinal fever.

The discrepancy between the local and the R.-G. population is now 86,608, and makes an appreciable difference in the birth- and death-rates. There were 23,649 births and 7082 mothers attended the prenatal clinics. The mortality from puerperal sepsis—namely, 3·8 per 1000 births, was the highest ever recorded. 602 cases of ophthalmia neonatorum were notified, but no damage to sight was recorded among the survivors.

Birmingham.

Dr. H. P. Newsholme reports many improvements in environmental hygiene. The hydrographical survey of the river Trent has been continued. The waters of the river Tame have been remarkably clear, but there has been no appreciable increase in the oxygen content. Small fish have, however, been observed in the river in the Witton area of the city. There has also been a big improvement in the oxygenation of the upper river Tame. An increasing number of authorities are favouring the principle of admitting liquid trade-waste into the sewers, and in one instance at Bilston the admission of this waste has actually improved the standard of purification. Several firms have constructed settling tanks, and in one instance the recovery of the oil has more than compensated the firm for the expenditure incurred. The Birmingham Tame and Rea Board is increasing its bio-aeration installation from a capacity of 7½ to 20 million gallons. The policy of abolishing tipping has been continued, and the percentage of refuse tipped has been reduced from 34 in 1924 to 10 in 1929. The percentage of standard dust-bins is now 99. A new scheme has been introduced for converting vegetable refuse, which is incombustible and especially liable to cause a nuisance if tipped, into a fertiliser. New by-laws have been drafted for that very unsatisfactory class of dwelling known as houses let in lodgings. An attempt was made by a local Bill in the spring of 1929 to obtain powers to restrict excessive rentals in these premises. Though the gravity of the abuse was not denied, the clause was rejected on the grounds that general and not local legislation was needed to deal with the problem. The new houses built numbered 4992, of which 3505 were municipal. There is still a considerable shortage which makes it difficult to close and demolish unfit houses. Houses with only a short lease of life have, therefore, to be repaired as an alternative to closure.

The examination of pasteurised milk shows that the "positive holder" gives better results than the "flow retarder" type, and that there is extreme variation with high bacterial count in the case of the "flash-point" type. The prices per pint of graded milks are given as: Certified, 5*d.*; Grade A (T.T.), 4½*d.*; Grade A, 4½*d.*; Grade A pasteurised, 4*d.*; Pasteurised. 4½*d.* The cows in the city sheds at the end of the year numbered 1532, and amongst them 19 were dealt with under the Tuberculosis Order—viz., 8 with tuberculosis of the udder, 9 with

" emaciation," and 2 with " chronic cough, &c." Of 1050 samples of milk examined 9·1 per cent. were found to be tuberculous as compared with 7·1 per cent. in the previous year. The 1050 samples included 77 from city dairies of which 5, or 6·1 per cent., were infected. The local scheme for encouraging tubercle-free herds does not progress. At the beginning of the year the scheme included 21 herds with 718 cows. Two new herds came in, but four were withdrawn owing to the high percentage of reactors. At the end of the year there were 19 herds with 688 cows in the scheme. Of 1774 cows tested in connexion with the scheme 1546 passed, 213 failed to pass, and 15 were doubtful.

The general death-rate, the infant mortality-rate, and the birth-rate were the lowest ever recorded. The average general death-rate for the central wards was 14·0, for the middle ring 10·8, and for the outer ring 8·7. The death-rate from respiratory diseases was for the central wards 2·43, for the middle 1·55, and for the outer 0·99. There were 54 known cases of small-pox with one death. Most of the cases were in connexion with a poor-law institution. There were 1552 notifications of diphtheria with 70 deaths, and Dr. Newsholme says it is obvious from a review of the cases that bad housing conditions, overcrowding, and insanitation play a large part in its propagation. It is not infrequent to discover several children at one and the same time occupying the same room all suffering from diphtheria. A disturbing feature is the insidious onset causing delay in obtaining medical advice. A circular has been issued to medical practitioners asking them to administer antitoxin in doubtful cases without waiting for the result of the swab examination.

Some increase in the prevalence of dysentery due to an organism of the Flexner type is reported. There were 84 known cases. An outbreak affecting nine children occurred in the ward of an institution. Another outbreak of 10 cases occurred in some houses let in lodgings and was attributed to an ex-soldier carrier. One affected child of 2 years, who was in a debilitated condition previous to infection, died. Two families were affected by food poisoning. In one case the infection was due to *Bacillus aertrycke*, and the vehicle of infection was "à la mode" beef. In this case there were two patients and one death. The beef had no objectionable odour or unpleasant taste. In the other family there were two deaths and the medium of infection was thought to be "pig scratchings" or black puddings. The diagnosis of encephalitis lethargica was confirmed in 41 cases. Twenty-three were males with 13 deaths and 18 were females with 9 deaths. The problem of post-encephalitis still remains one of urgency, and these unfortunates "drift as in-patients or out-patients from one hospital to another leading a life of continual misery." There is no substantial difference in the rate of infant mortality during the first fortnight after birth in the central, middle, and outer wards, and the same observation is applicable to the stillbirth rate.

A special inquiry into deaths from pneumonia *in children under 5 years by Dr. Ethel Cassie* brings out the fact that the common type of pneumonia seen in young children is dependent to a great extent on environmental conditions. Another striking point is the high incidence of bad health and especially of pulmonary tuberculosis among the parents of the affected children. The training course for health visitors established jointly by the University of Birmingham and the public health committee in the autumn of 1927 has proved most successful in encouraging a supply of properly trained health visitors for the district. The number of ultra-violet light clinics has been increased from five to nine, and 1375 children and 21 mothers received the treatment. The number of expectant mothers who made use of the medical help insurance scheme was 3008, and medical help was sent for in rather more than a third of the cases. The cost to the corporation works out roughly at 18*s*. per case for both insured and uninsured.

Both the incidence of ophthalmia neonatorum and the damage resulting from this infection were heavier in 1928 than in any recent year. There were 530 notified cases as compared with 409 in 1927. Of the affected infants 18 had scarred eyes, and of these four were rendered quite blind, three had grave impairment of vision in both eyes, and 11 had permanent damage to one eye, the sight being completely lost in three cases. The factors responsible for this increase in the incidence and the severity of the disease are discussed. There was coincidently an increase in both male and female cases attending the V.D. clinics for gonorrhœa. No changes have been made in the prophylactic precautions adopted against ophthalmia or in the hospital provision for the cases which occur. "The majority of the patients received out-patient treatment until or unless there was clearly need for in-patient treatment," and the experience of 1928 seems to indicate as stated in the report that "early and prompt admission to a hospital bed for all but the mildest cases is therefore to be recommended."

Liverpool.

Dr. A. A. Mussen reports that the city boundary was extended on April 1st, 1928, to include the parishes of Croxteth Park and West Derby. The area of the city has thus been increased from 21,219 to 24,772 acres.

The building of the new abattoir has been begun. The subsidy houses erected during the year were 2330 municipal, and 208 by other enterprise. In 1919 the Housing Committee began to erect houses in the suburbs, and up to the present 17,432 and 160 flats have been completed and 747 houses are in progress. The difficulty with regard to the removal of insanitary houses in the congested part of the city will be lessened by the erection of 200 tenements (in progress) in Melrose-road and 198 in South Hill-road, Dingle (completed). The Queen Anne-street area has now been approved. This site consists of 5¼ acres, upon which it is proposed to erect 408 houses, which will form another addition to the sanitary dwellings in the central area.

At the end of the year influenza deaths began to increase, the prelude to the most serious visitation of influenza since 1918–19. The pandemic began on the western seaboard of the U.S.A. in October, 1928, and reached its height on the Pacific Coast on Dec. 8th. A fortnight later it reached the Eastern seaboard and appeared in Glasgow on Jan. 12th. Shortly afterwards Northern Ireland and the continent were attacked. The epidemic definitely began in Liverpool in the third week of January and reached its height in the week ended Feb. 2nd, when the general death-rate was 37·8. Liverpool was fortunate in getting the epidemic over before the really severe weather, and suffered less than many other large towns. Room was made for the numerous pneumonia cases in the poor-law hospitals by the transference of other types of disease to the city hospitals. During the first quarter of 1928 there were two cases of small-pox. One attended a doctor's surgery and was promptly isolated; the other case was a child in a gipsy caravan. There was no further spread, and Dr. Mussen points out that the child population of Liverpool is relatively well vaccinated. During the year the city arranged with 12 adjoining local authorities to treat their small-pox cases in return for an annual retaining fee and an additional payment per case admitted. There were seven Liverpool cases of anthrax, four among handlers of hides, one of a female who had to handle East Indian wool, and two among tanners' labourers. During the past five years striking results have been obtained at the City Hospital, Fazakerley, by serum treatment; 31 cases treated all made a good recovery without the excision of the malignant pustule. During the same period three moribund cases were taken in and died within a few hours of admission. Of the two 1928 cases, which ended fatally, one was diagnosed too late and the other by his own neglect was admitted to hospital too late. Steps have been taken to inform the

Liverpool hide and skin trades of the successful results of the serum treatment. A bull suffering from anthrax was slaughtered in Cheshire and the carcass sent to the Liverpool abattoir. The Cheshire butcher who dressed the carcass was seriously ill for some weeks. Those who handled the meat at the Liverpool abattoir received preventive doses of the serum and remained well.

Good results are claimed for light treatment at the Carnegie centre and at the Children's Hospital for non-pulmonary tuberculosis, Leasowe; and the medical staff who treated tuberculosis at Fazakerley Hospital are convinced that "light treatment is of very definite value." All degrees of inflammation were included in the 545 notifications of ophthalmia neonatorum. The damage done included one blinded child and one with the sight of the right eye affected. The total births numbered 19,120 and 8702 expectant mothers attended the 28 prematernity clinics, which are held weekly in Liverpool. Dr. Mussen complains of the delay in notifying tuberculosis; 22 per cent. of the pulmonary cases notified died before the end of the year, and 216 of the 1148 deaths from tuberculosis were those of unnotified cases. The attendances of gonorrhœa cases at the Seamen's Dispensary have been much reduced, as a shorter time is required for cure and irrigations since the installation of electrical treatment apparatus.

The transport of milk by motor vehicles on the road is increasing and has many advantages. Thus the farmer has his empty churns returned direct to the farm and the dairyman is saved the expense of collecting his milk at the railway station. During 1928 there was a considerable increase in the quantity of designated milk. The cow population of Liverpool is 3947, and amongst them 25 cows with tuberculous udders were found. 488 samples of outside milk were examined and 34, or 6·9 per cent., were found to be infected with tubercle.

SCHOOL MEDICAL SERVICE.

Scarborough	Not stated.		1541	995	17·0

Liverpool.

THE immense improvement in physique and general health brought about at least partially by the activities of the school medical service is strikingly demonstrated in this report.

Dr. A. A. Mussen quotes from a report on the condition of the Liverpool school-children in 1907 descriptions of malnutrition, ill-clothing, and physical defect which seem incredible to-day. Dr. Mussen also reproduces statements from two head teachers, whose long experience enables them to recall the state of the children 20 years ago when teaching in a slum school was repulsive to many because of the dirt and its results. Quite half the boys were barefooted, and the teacher recalls the picture of "older boys carrying on their backs little chaps unable to walk because of festering sores on their feet." Another telling picture of the improvement is a graph showing the fall in the exclusions for verminous conditions, from over 950 in 1910 to under 20 in 1928. Dr. Mussen mentions some of the facilities now established for dealing with school-children, including residential open-air treatment in the committee's own institution at Woolton Vale, and the 30 beds reserved at Torpenhow, adding that there will be soon two new day open-air schools in the city. He makes special mention of the extensive and beneficial work carried out by the Committee's Inspector of Physical Training, the report of which appears as an appendix.

The care of pre-school children is now recognised as essential, and in 1927 arrangements were made for their treatment when suffering from otorrhœa or squint. Parental ignorance prevents more extensive dental treatment, the proportion of parents accepting treatment being less than three-fifths of that for the whole country. The charge (6*d.*) may have been responsible in some cases and the extension of free dental treatment is worth considering. But ignorance is the real difficulty in this matter and also in connexion with the refusals of the facilities afforded in the stammering class. In another connexion difficulty is caused by the mental attitude of the children themselves; 34 per cent. of those who had been provided with glasses were found not to be wearing them, the proportion rising to over 50 per cent. in certain schools. Often these children are afraid of ridicule. However, the marked change of attitude of parents and children to school medical work noted in Dr. Mussen's introductory pages will no doubt extend and the early removal of the obstacles still in the way of complete success can be anticipated.

Nottingham.

The earlier pages of the report by Dr. E. M. Wyche are taken up by photographs of facilities for treatment and examples of the fine results. Soon after comes a diagram showing the comprehensive scheme for diagnosis, treatment, and care, and the introduction to the text of the report shows how this organisation has been gradually built up. Among the more recent extensions is the orthopædic scheme dating from 1925. Two gaps remain in this work; the lack of a special school for the 377 cripples still in elementary schools, and the difficulty in securing enough beds for orthopædic cases; this latter difficulty is likely to be obviated shortly, when the new Harlow Wood Orthopædic Hospital is completed. An apparatus for ultra-violet ray therapy was installed in 1927, and an interesting account is given of the benefits obtained in certain cases. Plans are under consideration for a large open-air recovery school, a new minor ailment clinic, and an additional special school for 100 mentally defective children. Except for a school for physical defectives, which is lacking, there will soon be almost complete arrangements for care and treatment in the city, where, moreover, the value of the clinics is being increasingly realised by the private practitioner. A scientific study of the problem of mental deficiency made by Dr. A. A. E. Newth suggests that bad scholarship, poverty, and large families tend to be associated.

Cambridge.

The percentage of defects found at routine inspections in Cambridge is below the average for the country and so are the numbers of some of the groups of exceptional children. In any district this circumstance may be due to fortunate local conditions or to variations in the standard of ascertainment of defects. This year's figures are not quite so low as those of previous years. Dr. A. J. Laird attributes the increase to the larger number of children suffering from enlarged tonsils, adenoids, anæmia and debility, due, in his opinion, to the recent increased prevalence of measles, scarlet fever, and diphtheria. The general physique of the Cambridge children is very good and is still improving, but the number of delicate children (397) is very high, so that there was ample justification for the provision of an open air school in July.

The dental scheme, under the direction of Mr. W. Baird Grandison, is so thorough that every elementary school child in Cambridge has the opportunity each year of dental inspection and treatment, and in 1928 out of the 6266 children in average attendance, 6080 saw the dentist and 2996 received treatment. As a result of good work extending back for 21 years, the dental condition of the children has steadily improved, 34 per cent. of them had, this year, no decay in either dentition and there was an average of only 4 unsaveable permanent teeth among batches of 100 children. 886 children took no advantage of the facilities offered. Mr. Grandison thinks that this was due, *not so much to antagonism or ignorance as to* inconvenience—for example, the mother might find difficulty in accompanying the child at the time appointed.

With such figures as 94·0 of sound temporary teeth after treatment, those responsible may be gratified by the success of the Cambridge dental scheme.

Scarborough.

Dr. S. Fox Linton introduces a detailed report by Dr. Anne Roxburgh. Scarborough is a town with rather a small child population, and there are some fortunate local circumstances and energetic social workers. The small numbers have perhaps been the reason for the absence of special schools; accommodation has been found for several defective children in institutions belonging to other authorities. There is no open-air school, nor is it deemed so essential as in the large and industrial towns; but for playing fields a piece of ground has been levelled on the Castle Hill and a large field has been rented by the Education Committee on the Northstead estate. The authority does not provide spectacles gratuitously; help is given to the poor children by the Amicable Society, often repaid by the parents in small weekly amounts. This Society also supplies cod-liver oil, milk, and free meals when needed. There are few cripples, so that an extensive orthopædic scheme is not wanted; but a clinic is held at the local hospital, attended by the orthopædic surgeon, Dr. H. L. Crockatt, and a massage sister. Institutional treatment is obtained when required at the Kirbymoorside Orthopædic Hospital. Cases of chronic deformities, such as those produced by old infantile paralysis under treatment by private practitioners or at the hospital, may need massage. This the poor can obtain by the help of the Council of Social Service, the parents paying what they can towards the cost.

Some at least of the reduction in the number of infantile deformities may be due to the activity of the infant clinic, where the health visitor has the assistance of a strong body of voluntary workers; several cases of early rickets are at present under treatment there. Another factor for good is doubtless the nursery class, at which the infants are kept under close medical supervision. X ray treatment for ringworm will be provided by a private arrangement with a skin specialist in the town.

Though there is no special M.D. school, there is a really adequate class for dull and backward, under a specially trained teacher, who has this year been given an assistant. A Council of Social Welfare, working in conjunction with the Yorkshire Association of Mental Welfare, takes over the after-care of children leaving this class. While in many branches of the work the ordinary official methods have not been developed, keen unofficial agencies have creditably filled the gap.

MENTAL HOSPITAL REPORTS.

THE 132nd report of *The Retreat, York*, records the gratifying fact that during the year 1928 over 60 per cent. of the patients admitted came as voluntary boarders, and the medical superintendent concludes that the era of the certified lunatic is drawing to an end. On Dec. 31st there were 210 patients on the books, the number of admissions (126) being the highest on record. The recovery-rate was 25 per cent., which is a high figure for the standard in use. A patient is only put in the "recovered" group when he is adjudged fit to resume his ordinary occupation without further supervision. The death-rate was 8·2 per cent. The general health was good, except for an outbreak of very mild paratyphoid fever which affected six patients and one nurse. A house was taken at Whitby for the summer months, and was much appreciated. The further development of occupational therapy is being considered, and every effort is made to induce the patients to share in their own entertainment. Fifteen patients have parole outside and 34 inside the grounds. The main part of the building had to be re-roofed last summer; the slates taken away were the original ones put on in 1793. Fourteen male and 20 female nurses are certificated in mental nursing; a sister, who was appointed matron of the Gloucester County Mental Hospital last year, was the seventh Retreat official to be promoted to a matron's post within six years.

James Murray's Royal Asylum, Perth, published its 102nd annual report for the year 1928–29. Ninety patients were admitted during the year—a record number—and the total on the books on March 31st was 192, an increase of 55 in four years. This increase has severely taxed the accommodation of the hospital, and a self-contained and detached reception block for 40 patients is to be built. The beds will be about equally divided between private rooms and dormitories, and the block will have its own nursing and domestic staff. There will be a surgery and dental room, clinical rooms, a laboratory, facilities for hydrotherapy and continuous baths, and an electrical treatment room with X ray apparatus and ultra-violet lamps. Acute cases will be sent to this block. The building has been so planned that another one like it can be erected near by in a few years if need arises. Many of the patients—over 62 per cent.—were admitted on a voluntary basis, and of these rather more than two-thirds were able to leave hospital restored or improved. Only about half the certified patients were discharged recovered. One general paralytic, treated by malaria followed by intensive antisyphilitic medication, has now been managing a successful business for 18 months. The death-rate was 9 per cent., and post-mortem examinations were made on half the fatal cases. The staff suffered a good deal from sickness during the year, but the hospital was remarkably free from epidemic disease despite the severe weather; there was only one case of influenza and no tonsillitis. A long series of patients was treated by protein shock and another series by ovarian extracts, but the results were confused and uncertain, as were also the results of ultra-violet therapy. Septic foci have been sought and treated, and a number of urinary antiseptics were tried. The occupational therapy department was attended by a great many patients; rug-making, basket-work, leather-work, and wood-carving all attract much interest. Open-air treatment is extensively used. The dairy herd has been disposed of; the fruit and vegetables did fairly well. A good deal of renovation has been carried out, and old-fashioned casements have been replaced by large panes or vita-glass. In January the carriages were replaced by a 24-h.p. seven-seater Austin limousine. Nine nurses sat for the R.M.P.A. certificate and were all successful, but there is a dearth of candidates for the State certificate.

At the beginning of this year there were 668 patients in the *City of Cardiff Mental Hospital*, an increase of ten on the previous year. The death-rate was 9·26 per cent. and the recovery-rate 38·7 per cent. The general health was good; there were three cases of tuberculosis, three of erysipelas, one of scarlet fever, and one of paratyphoid B. General paralysis was the cause of 31·84 per cent. of the deaths. Autopsies were held in all cases in which permission could be obtained. The dental surgeon has attended regularly throughout the year; the gynæcologist has examined 32 patients and the aurist 53. A wireless set has been installed; its cost was largely borne by members of the Japanese Community in London, in recognition of the care of certain Japanese patients in the hospital. The out-patient clinic in psychiatry is held weekly at the Cardiff Royal Infirmary, and the secretary attends there to follow up discharged cases. Various physiological tests are carried out on all suitable new patients, and investigations are being made into the condition of the vegetative nervous system, the blood cholesterol and hydrogen-ion concentration, and the carbon dioxide combining-power of plasma.

All but three of the male wards are nursed by women. Three nurses and one attendant passed the final State examination during the year.

There were 1081 patients in the *County and City of Worcester Mental Hospital* at *Powick* at the end of 1928. The recovery-rate for the year was 32·6 per cent. and the death-rate 4·7 per cent., the principal causes of death being old age (26 per cent.), heart disease (20 per cent.), and phthisis (12 per cent.). Autopsies were held on 68 per cent. of cases. Apart from a mild epidemic of influenza in the spring, the general health was good. Only six patients, all men, have parole beyond the estate; 32 men and seven women are free within the grounds. A dentist visits the hospital once a fortnight. The farm showed a profit of over £600 on the year's working, but does not supply enough milk for the needs of the institution. The visiting commissioners express anxiety about the use of nearly 200 twelve-ounce tins of condensed milk weekly, especially as margarine and not butter is given for breakfast and tea. The hospital is handicapped by having no electricity and very few clinical rooms. The committee is considering the introduction of an electric supply. One male and two female nurses gained the R.M.P.A. certificate during the year.

The report of the *Brighton County Borough Mental Hospital* at *Hayward's Heath* has as frontispiece an aerial photograph of the institution. There were 895 patients in the hospital at the end of 1928. Forty-five of the 264 admitted were over 60 years of age, and the recovery-rate was therefore a little lower than last year—36·6 per cent. The death-rate was 9·15 per cent. Twenty patients suffered from tuberculosis, but otherwise the general health was good. Eight general paralytics were sent to Hellingly for malarial treatment, but only one showed any improvement. Forty-six patients have been on full parole and 52 more on parole within the grounds. The hospital is crowded during the day, and the committee are considering the purchase of a neighbouring estate for an admission hospital. The dentist attended 685 patients during the year and extracted 757 teeth. One ward on each side is administered on the open-door principle. Ultra-violet ray treatment has been found valuable for convalescents. The out-patient clinic at Brighton served 438 patients, including 98 new ones during the year, and has done very good work. Four nurses obtained their R.M.P.A. certificate, and it is hoped that improvements in accommodation for the staff will diminish the matron's difficulty in securing suitable female nurses.

The *West Sussex County Mental Hospital* (*Graylingwell, Chichester*) had 877 patients on the books at the end of 1928, an increase of 65. The hospital is already uncomfortably overcrowded, and another two years must elapse before the new buildings will be available. The provisional scheme includes a block for 115 women, a villa for 50 women, an admission hospital for 35 women, and a nurses' home. Meanwhile the heating system of the old blocks is to be modernised. The medical superintendent hopes that the new admission hospital will, by the time it is ready, be allowed to receive patients on a voluntary basis. The death-rate was 6·1 per cent. and the recovery-rate 32·7 per cent. The general health throughout the year was good. There was one case of severe chicken-pox and a few cases of influenza. Two patients and the medical superintendent contracted typhoid fever. Five major operations were performed and one general paralytic was sent to Knowle for malarial treatment, but he did not improve. During the summer the usual picnics to the seaside were arranged. Several patients have been allowed out on leave for periods varying from a day to three weeks and parole beyond the estate is given to 23 patients, and within the grounds to 50 more. Three male and five female wards are administered on the open-door principle. Two nurses and one attendant obtained their R.M.P.A. certificate and one nurse passed the final State examination. The medical superintendent mentions the excellent work of the nursing staff in the face of peculiar difficulty incident to the overcrowding.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED AUGUST 24TH, 1929.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 139 (last week 120); scarlet fever, 1678; diphtheria, 793; enteric fever, 89; pneumonia, 490; puerperal fever, 40; puerperal pyrexia, 95; cerebro-spinal fever, 8; *acute poliomyelitis, 14*; *acute polio-encephalitis*, 3; encephalitis lethargica, 24; dysentery, 6; ophthalmia neonatorum, 110. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on August 27th–28th was as follows:—Small-pox, 144 under treatment, 24 under observation (last week 147 and 1 respectively); scarlet fever, 1313; diphtheria, 1430; enteric fever, 14; measles, 325; whooping-cough, 228; puerperal fever, 26 (plus 11 babies); encephalitis lethargica, 123; poliomyelitis, 1; "other diseases," 20. At St. Margaret's Hospital there were 14 babies (plus 8 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 3 (0) from enteric fever, 18 (5) from measles, 3 (1) from scarlet fever, 24 (2) from whooping-cough, 20 (3) from diphtheria, 67 (11) from diarrhœa and enteritis under two years, and 17 (2) from influenza. The figures in parentheses are those for London itself.

Of the deaths from diarrhœa 7 each were reported from Liverpool and Hull, 6 from Birmingham, and 4 from Sunderland. Liverpool recorded 5 deaths from whooping-cough and Manchester 3. The deaths from enteric fever occurred at Wood Green, Sheffield, and Cardiff.

The number of stillbirths notified during the week was 259 (corresponding to a rate of 37 per 1000 total births), including 55 in London.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

A Memorial to Sir William Thompson.

A MEETING of the friends of the late Sir William John Thompson has been held to consider the establishment of a memorial to him. The meeting decided to appeal for funds to establish a tuberculosis village settlement in connexion with the Peamount Sanatorium, Co. Dublin. Sir William was greatly interested in anti-tuberculosis work and was, indeed, one of its pioneers in Ireland. He had been honorary treasurer of the Peamount Sanatorium since its foundation some 17 years ago, and had been interested for some time in the project of adding to its utility by a tuberculosis settlement. If adequate funds are forthcoming no doubt the Papworth model will be followed, and the Memorial Committee arranged with Dr. Varrier Jones to give a lecture a few days ago on his work at Papworth. At the sanatorium he addressed a large audience, including many of the patients, and having described the object and achievement of Papworth, he showed a large number of illustrative lantern slides.

Examination of Milk.

The difficulties arising in the examination of milk in regard to the amount of fats present were exemplified in two cases which came recently before one of the Dublin magistrates. A milk-dealer was prosecuted by the Dublin Corporation on the ground that certain milk offered for sale contained only 2·7 per cent. of fats, the legal standard being 3 per cent. Evidence was submitted, in defence, of a finding of 3·67 per cent. of fats in another portion of the same specimen. The magistrate adjourned the case for the report of the State analyst on the third portion of the specimen. His examination found 4·9 per cent. The magistrate dismissed the case with costs. In a similar case the three analyses gave percentages of 2·4, 3·59, and 6·7. This case also was dismissed with costs.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

Investigation of Maternal Mortality.

THE Department of Health for Scotland has taken an important step to secure the closer investigation of maternal deaths during pregnancy or within a month after the termination of it. This was one of the many recommendations made by Lord Salvesen's Committee on Puerperal Morbidity and Mortality, which reported to the Scottish Board in 1924. Why it should have taken five years to give effect to the recommendation may not be easy to explain, but the new department has lost no time in creating the necessary machinery and in issuing instructions. The form of death certificate in use in Scotland has now, under the powers of an Order in Council dated June 8th, 1929, been altered "to provide for a statement by the medical attendant if, in the case of a married woman, the death occurred during pregnancy or within four weeks of the termination of pregnancy." The Registrar-General for Scotland has notified the alteration in the certificate to the local registrars and authorised them to supply medical officers of health, when requested to do so, with a special return in a prescribed form in respect of cases in which the question as to pregnancy is answered in the affirmative. Registrars will be prepared to make these returns from Oct. 1st next. The second difficulty is the question of method. Fortunately, Aberdeen's ten years' systematic investigation (published by the Scottish Board of Health last year) provides a model and the Department now issues an elaborate form and a memorandum of directions to every medical officer of health. This is the most important step yet taken in Scotland to get to grips with the causes of deaths associated with pregnancy. There is every hope that practitioners will coöperate as they did in Aberdeen, since every care is taken to keep the investigation of individual cases strictly confidential.

Mental Defectives and the Public Safety.

At a Glasgow sitting of the High Court of Justiciary, a plea of insanity in bar of trial was accepted on behalf of a young seaman charged with shooting and murdering a woman in a Glasgow public-house. But insanity was not the whole case. Dr. Gilbert Garry, Duke-street Prison, considered the prisoner of unsound mind and unfit to plead; he did not appear to appreciate the difference between right and wrong. Dr. J. H. Macdonald, of Hawkhead Mental Hospital, regarded him as a moral imbecile and insane. Dr. R. D. Clarkson, under whose charge he had been at the Royal Larbert Institution, said the man had no sense of moral obligation and that he (Dr. Clarkson) had, without effect, recommended that his detention at Larbert should be extended. He had examined the man that day and found him in the same mental condition as when he was a boy. He declared that the accused, for the protection of others, should have been placed under proper supervision and control from the time he was 8 or 9 years old right through his life.

The Lord Justice-Clerk (Lord Alness), who tried the case, made some observations on it at an informal banquet given by the Lord Provost and magistrates. It raised the question, he said, whether adequate machinery existed for preventing persons being at large in the community when their mental state rendered them a danger both to themselves and to others. In this case an individual was found to be of unsound mind and unfit to plead. He was also described as having been in the same mental condition when released some time before from a mental institution. In that mental state, apparently, he went about the world, with the result that he shot a young woman dead, and attempted also to shoot a man. That, to his mind, seemed a disquieting state of affairs. He was not suggesting blame to anyone in connexion with the case, but he did suggest in the interests of the safety of the public consideration by the appropriate authorities whether machinery could not be devised to prevent the recurrence of such deplorable incidents.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

White House Conference on Child Health.

President Hoover's interest in child health has long been known in America. His presidency of the American Child Health Association was but one indication of this interest, and another is his intention to summon a White House Conference on the health and protection of children. The first meeting of the planning committee was held in Washington on July 29th and was addressed by President Hoover, who hopes that the policies adopted by that Conference will be followed up by definite organisation throughout the country. Progress in this direction must for the most part be made by voluntary action and by activities of local government, but the Federal Government will attempt to secure some measure of unity as to view and as to programme.

Every subject bearing on child health, including the difficult subject of child labour upon which Congress has twice attempted to legislate without success, is to be brought under consideration. A sum of half a million dollars from private sources has been placed at the President's disposal to cover the expenses of the preliminary committees and for investigations which they may require. The Secretary of the Interior, Dr. Ray Lyman Wilbur, a past president of the American Medical Association, will have general charge of the Conference. The planning committee itself is drawn from organisations of quite diverse interests, and has a personnel which will inspire confidence.

Diploma Forgeries in Illinois.

Five men have recently been indicted before a grand jury in Chicago for the sale of licenses to applicants who were not properly qualified to practise medicine. True bills were returned on July 30th. The chief among this group is W. H. H. Miller, who was formerly director of the State Department of Education and Registration. This man was found guilty of selling licenses while in office, and eventually discharged, but is said to have claimed since his discharge that he retained all his influence in the department. The evidence is said to indicate that more than 1000 forged licenses have been issued. One man, said to be in possession of such a license for which he is supposed to have paid $1500, has already been arrested. He was found working as an orderly at the West End Hospital. A blank abortion release slip is alleged to have been found in his pocket.

Silver Polish Poisoning.

Several cases of acute poisoning of guests in hotels have been reported to the New York State Department of Health and are under investigation. A typical severe case is that of a man, aged 45 years, who was seized suddenly with nausea and severe colic. From midnight until 2.30 A.M. he vomited continuously, and thereafter suffered from tenesmus, diarrhœa, nausea, and continued retching. The patient was now covered with profuse perspiration, the skin cold, pallid, and cyanotic. The pulse was rapid, of low tension, and irregular. After three hours of active treatment with applied heat, hot coffee by mouth, and caffeine hypodermically, the shock subsided. One-eighth grain of morphine was placed under the tongue and the patient went to sleep. Recovery was uneventful. Three other persons who had partaken of the same evening meal had similar though less severe symptoms. The State Department of Health has found that in every case where these acute poisonings have occurred the hotel management is in the habit of employing a silver polish manufactured by a New York firm. Analysis of this firm's products gives in every case a positive cyanide reaction. One silver polish put out by them was found to contain as much as 20 per cent. of sodium cyanide. Hotel managers who have ceased to use the polish on advice from the Health Department report a cessation of symptoms among their guests.

Lethal Possibilities of Vibratory Massage.

As Sandow exercises were the fashion in England a generation or so ago, at the present time in the United States there is a vogue for vibratory massage. The modern fad is mechanical—driven by electric motor. Apparently it is not without its dangers. The case is recently reported of a man who after an hour's "exercise" in a gymnasium under the supervision of a "physical director" developed an acute soreness in the abdomen, about an inch to the right of the umbilicus, some weakness and dizziness. He had, it seems, used an electrically driven vibrating massaging belt applied to his abdomen for the space of ten minutes. Next day he passed about 15 well-formed tarry stools, after which he was short of breath and of blood, and called his physician. The latter, as well as a consultant, believed that he was bleeding from a duodenal ulcer; the consultant had at that time in hospital a patient whose ruptured appendix was attributed to the use of a similar apparatus. The committee on physiotherapy of the Medical Society of the County of New York has on record a case of severe hæmorrhage of the bladder, resulting from five minutes use of an exercising machine, and is appealing through its chairman, Dr. Richard Kovacs, for information regarding other accidents that may have resulted from such machinery.

Diet in Tuberculosis.

The opinion of 36 prominent phthisiologists has been ascertained recently on the subject of diet in tuberculosis by Dr. John B. Hawes, of Boston, by the questionaire method. The idea that the patient should be stuffed seems now to have been universally abandoned. Extra meals are, on the whole, regarded with disfavour. Egg-nogg was the subject of considerable disagreement and violence of attack on the part of some specialists, rather surprising since no reason is offered for their aversion to this particular combination. As for milk, most of those questioned favoured a maximum allowance of one quart given daily—with, rather than between, meals. A good deal of emphasis was laid upon the importance of rest immediately before and after meals. Some were strongly of the opinion that five or six glasses of water should be drunk daily, others that most patients drink too much water. It is difficult to judge of the value of these opinions without knowing on what principles they were founded.

Governor Roosevelt creates a Spa.

The Governor of New York State has decided to exploit the resources of the State in mineral waters, and has selected Saratoga as the site of a model spa. The town is already a fashionable resort in beautiful country, not many miles south of Lake George, and devoted to horse-racing. It will be of interest to observe whether those in search of health will be deterred by the present somewhat noisy display of wealth or whether the Governor's plans will overshadow the existing attractions A medical advisory committee, including the president and the director of the New York Academy of Medicine, and the professors of medicine at Cornell University and the Albany Medical College, has been appointed to assist the State Commission charged with the development project. In a speech to the annual conference of Health Officers and Public Health Nurses the Governor explained the scope of his ambition. It is his hope that Saratoga may do great good for many human ills of the people of the State, and, moreover, point the way so that other States and other mineral springs can be developed along scientific and medical lines. From the Adirondacks to Georgia there are wonderful springs on both sides of the range, and both in the west and middle west there are springs going down through the Ozark mountains and borders of Oklahoma and Texas. Those of the Rockies extend down to Montana and Arizona, and in the Allegheny Mountains. The development of all these natural advantages may follow the Saratoga scheme should this prove a success.

Dental Research in Alaska.

The first complete dental equipment, including X rays, to be sent to the Eskimos of Northern Alaska is now on its way. The expedition is in charge of Dr. Leuman M. Waugh, the associate dean of the school of dental and aural surgery of Columbia University, who has been given a temporary commission in the public health service.

Appointments.

Dr. David Rapport, who has been appointed to the chair of physiology at Tufts College Medical School, graduated from Harvard in 1912, and from the Harvard Medical School in 1916. During the next two years he worked under Sir Thomas Lewis on the effort syndrome in soldiers, and has since taught at Harvard, Cornell, and Western Reserve Universities. Dr. William G. Gallie has been appointed to the chair of surgery at the University of Toronto. He gave the Hunterian lecture before the Royal College of Surgeons in 1924 on Transplantation of Fibrous Tissues in the Repair of Anatomical Defects.

NOTES FROM INDIA.

(FROM OUR OWN CORRESPONDENT.)

The All-India Medical Council.

THE proposed Bill "to establish a Medical Council in India and to provide for the maintenance of a British Indian Medical Register" met with a further check last month. The conference of Provincial Ministers of Public Health, Surgeons-General, and Inspectors-General of Civil Hospitals, assembled at Simla to consider the proposed measure, showed considerable opposition to the Bill. Although the deliberations of the conference have not been made public it is evident that the various provinces are unwilling to transfer their present powers of regulating medical education to a centrally constituted body, despite the fact that adequate provincial representation is provided for in the proposed scheme. Nevertheless, the case for the immediate formation of an all-India council is a strong one. The suspicion that such a council would arrogate to itself the function of prescribing the courses and curricula of the universities and medical schools is unfounded. It would naturally have to be satisfied of the adequacy of the standard of instruction in any given training centre before recognising its degrees for registration, but the onus of drawing up curricula so as to conform to the standard of proficiency set up by the council would rest with the various educational authorities concerned.

Tuberculosis in Bengal.

The gravity of the tuberculosis problem in Bengal may be realised when it is stated that there are in the neighbourhood of 800,000 cases in that province. Of these, about 200,000 require sanatorium treatment and there is no provision whatever for their accommodation. Dr. A. C. Ukil in a recent address urged the immediate necessity for the establishment of provincial organisations to study the disease and to devise measures for its prevention. A beginning has already been made by the establishment on a purely voluntary basis of the Tuberculosis Association of Bengal.

A New Leprosy Publication.

The Indian Council of the British Empire Leprosy Relief Association have decided to issue quarterly a small brochure entitled Leprosy in India, which is intended to form a means of communication between leprosy workers in this country. The first number, which has just come to hand, contains informative articles on the objects of the council, on a leprosy survey in Travancore State, and on anti-leprosy work in Bihar and Orissa and in Burma. These quarterly notes are distributed free of charge to those taking an active part in the work of eliminating leprosy from India.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Capt. H. J. Chater is placed on the Retd. List.

A. M. Lawrence-Smith and B. St. John Lyburn to be Surg. Lts.

The following appointments are notified: Surg. Comdrs. M. S. Moore to *Vindictive*; J. F. Haynes to *Victory* for R.N. Hospl., Haslar; P. L. Gibson to *President* for R.A.F. Medical Officers' Course; G. L. Ritchie to *Lowestoft*; D. C. Eglington to *Pembroke*, for R.N. Hospl., Chatham; and J. F. Place to *Pembroke*, for R.N. Barracks, Chatham.

Surg. Lts. R. C. Webster to *Shropshire*, and J. Johnston to *Lowestoft*.

Surg. Lt.-Comdr. J. F. Ainley to be Surg. Comdr.

ROYAL NAVAL VOLUNTEER RESERVE.

Surg. Lts. J. B. Oldham to *Victory* for R.N. Hospl., Haslar, for training; E. C. Johnston, commission terminated on entry into R.N.; R. W. H. Tincker to *Pembroke*, addl., for R.N. Barracks, Chatham, addl., for 14 days' training; and H. M. Willoughby to *Victory*, addl., for R.N. Barracks, Portsmouth, addl., for 14 days' training.

Surg. Lt. H. M. Petty to *Pembroke*, for R.N. Barracks, Chatham, for training.

A. J. W. Beard entered as Proby. Surg. Sub-Lt. and attached to the London Division, List 2.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. R. L. Popham, having attained the age for compulsory retirement, is placed on retd. pay.

Maj. T. B. Moriarty, D.S.O., to be Lt.-Col., vice Lt.-Col. R. L. Popham to retd. pay.

The undermentioned to be Lts. (on prob.): D. A. O. Wilson, T. R. J. P. Kerwick, T. G. D. Coneys, J. G. Black, A. N. B. Odbert, Temp. Lt. C. A. Levy (and relinquishes the temp. rank of Lt.), and S. W. K. Arundell.

Lt. A. H. Weston, from the R.A.M.C., T.A., to be Lt. (on prob.).

Lt. (on prob.) T. G. D. Coneys is secd. under the provisions of Art. 205, Royal Warrant for Pay and Promotion, 1926.

Temp. Lt. H. T. Chiswell relinquishes his commn.

ARMY DENTAL CORPS.

Capt. W. Philp to be Maj.

Lt. (on prob.) E. C. Irish is confirmed in his rank.

ARMY RESERVE OF OFFICERS.

Lt.-Col. R. L. V. Foster, having attained the age limit of liability to recall, ceases to belong to the Res. of Off.

TERRITORIAL ARMY RESERVE OF OFFICERS.

Maj. S. McCausland, having attained the age limit, relinquishes his commn. and retains his rank.

ROYAL AIR FORCE.

Flight Lt. G. H. H. Maxwell is promoted to the rank of Squadron Leader.

COMMISSIONS IN THE ROYAL ARMY MEDICAL CORPS.

The following have been granted commissions as Lieutenants on probation in the Corps:—D. A'Brook, M.R.C.S., University College Hospital; D. A. O. Wilson, M.B., Queen's University, Belfast; T. R. J. P. Kerwick, M.B., University College, Dublin; T. G. D. Coneys, L.R.C.P. & S.I., Royal College of Surgeons, Dublin; J. G. Black, M.B., University of Aberdeen; A. N. B. Odbert, M.B., Trinity College, Dublin; C. A. Levy, M.R.C.S., St. Thomas's Hospital; S. W. K. Arundell, M.R.C.S., Middlesex Hospital; A. H. Weston, M.B., University of Edinburgh; and E. A. Wilson, M.B., University of Edinburgh. Two of these officers have been seconded for the purpose of completing appointments in civil hospitals.

Correspondence.

PENAL TREATMENT FOR NERVOUS DISORDER.

To the Editor of THE LANCET.

SIR,—That a police magistrate should consider the penal treatment of a patient suffering from a nervous disorder proper and fitting is not very surprising, but it is rather disturbing to find that you should approve of such a proceeding as you do in your issue of August 17th (p. 351).

The case to which I am referring is that of a man who had been addicted to morphia to the extent of 15 grains a day. Under treatment this was reduced to ½ grain, and at this point the patient was discharged from treatment through no fault of his own. He was given a prescription for one single half grain of the drug. What was the man to do? Everyone knows that such a patient must somehow obtain more morphia. He seems to have regularised his position later on by getting prescriptions from other doctors, but unfortunately before doing so he falsified this prescription, and so illegally got possession of 12 grains. For this he received three months' imprisonment, with your approval.

The first point that strikes me is this: is imprisonment likely to cure such a patient? I know of one patient who was sent to prison for the crime of illegal possession of morphia, and he was not cured. The drug was cut off at once, and those who know anything of the morphia craving will realise what that means. On the day of his release, he succeeded in buying the drug without difficulty. Again, ought we doctors to applaud the fixing of the stigma of imprisonment on a patient; ought we not rather to endeavour, as we do for the insane, to lead the authorities to see that stigmas are good for nobody, and that patients will do better if treated without them.

To seduce a person into taking morphia is a grave moral offence, and is rightly punishable by law; but in what sense, legal or moral, is morphia addiction an offence. This man had not led anyone into the morphia habit, and I am unable to agree with you in your dictum that "The case shows the administration of the law in the best interests of the accused."

I am, Sir, yours faithfully,

T. A. ROSS.

Swaylands, Penshurst, Kent, August 21st, 1929.

CHORDOTOMY IN THE TREATMENT OF OSTEOARTHRITIS OF THE HIP.

To the Editor of THE LANCET.

SIR,—I was much impressed by Mr. Bankart's admirable paper in your issue of August 24th (p. 378) on the treatment of this condition by division of the spino-thalamic tracts. Before deciding to carry out the operation myself, however, I should like to learn from Mr. Bankart a little more detail. For example, how does he recognise the part of the spinal cord requiring section, and how does he divide it? In my edition of "Cunningham's Anatomy" (which I admit is dated 1900) it is stated that "as the spino-thalamic tract ascends in the cord its fibres are not gathered into a compact strand, but are more or less loosely scattered in the lateral column." Does Mr. Bankart divide as much as one-fourth of the spinal cord, and how does he guard against the danger of producing paralysis?

One other point: Mr. Bankart does not mention a method of treatment which is most useful in these cases—namely, giving the patient a pair of crutches. If the case be one in which there is no pain when the patient [illegible] recumbent [illegible] entire[illegible] prevent the [illegible] is up an[illegible]. Strange to [illegible]nce of [illegible] in this [illegible] appears to favour the production of ankylosis, and when this has become sound all pain in the hip vanishes and the crutches can be discarded. Though this may take years the cure of the pain is certain.

I am, Sir, yours faithfully,
PAUL BERNARD ROTH.
Welbeck-street, W., August 24th, 1929.

To the Editor of THE LANCET.

SIR,—The operation of chordotomy clearly has come to stay, and there is no difficulty in enumerating the conditions in which for the relief of paroxysms or everlasting pain the operation will now probably be performed. The skill of the surgeon with his full and bloodless exposure makes the operation appear easy enough. Good nursing, as a rule, does the rest. But it is the physician who probably will continue to shoulder the prime responsibility. With experience of antero-lateral tract section and of medio-longitudinal section (suggested first, I believe, by Dr. J. G. Greenfield) I think that the latter operation is more easily performed than the former; also it appears to be based on a sounder anatomy. The anterior spinal artery is not injured by the skilled surgeon. It is important that the decision to operate shall be made long before the patient is worn out by his pain, by drugs, or by time. I have under observation at the moment a man on whom complete medio-longitudinal chordotomy (traumatic spina bifida) was performed a few weeks ago through four segments of his thoracic cord for the relief of crises. He appears to have therefrom no impairment of sensibility whatever to thermal stimuli.

I am, Sir, yours faithfully,
HILDRED CARLILL.
Harley-street, W., August 24th, 1929.

THE NEW VACCINATION ORDER.

To the Editor of THE LANCET.

SIR,—In regard to the new Vaccination Order, I recall that the most successful vaccinations I ever witnessed were performed by a former colleague of mine, the late Arthur Caesar, public vaccinator for the Eastern District Hamlet of Mile End Old Town. With the lower part of the cutting edge of a broad spear-headed lancet held almost flat to the skin, by a gentle incising movement he slightly lifted the epidermis forming, as it were, a valve shutting in the lymph. He never scratched with the point, scarcely drew blood, was nearly always successful, and very little inflammation followed the operation.

I am, Sir, yours faithfully,
FREDK. WM. ALEXANDER,
At one time Public Vaccinator, Western District Hamlet of Mile End Old Town; formerly M.O.H., Metropolitan Borough of Poplar.
Teddington, August 27th, 1929.

ANTIDYSENTERY BACTERIOPHAGE.

To the Editor of THE LANCET.

SIR,— As the author of the paper "Antidysentery Bacteriophage in the Treatment of Bacillary Dysentery" published in THE LANCET of August 10th, may I be permitted to reply to some of the points of criticism raised in your leading article on the subject in the same issue.

The impression created by your article in regard to my clinical results in the treatment of dysentery with bacteriophage is, that there was an initial "maximum beneficial effect" in just over 50 per cent. of the cases treated. This calculation and the expression of it can only be arrived at if we take a phrase from its context and ignore the rest. It thus represents only half, and, as may be agreed, the less encouraging half of the facts. In my "severest possible analysis" of the results, I was able to show that there were in all only 17 results that could be considered as failures, leaving 45 successes, which represents "a minimum percentage success for the treatment of 72·6." As I believe, I made sufficiently clear, this calculation is based on a reasoned interpretation of the facts, and it is the only one valuable. To it, I would add my considered judgment that "the general result of phage treatment for bacillary dysentery appears very much in its favour" as is borne out by the fact that more than "70 per cent. of the cases showed a well-defined and rapid improvement."

It is unfortunate that, through lack of space, you had to sacrifice the Table of "Clinical Records" accompanying my paper, since you appear to cast some doubt on the subsequent recovery of the cases in which the treatment was even most successful. This table would, I think, have enabled you and your readers to appreciate better the course of events from initial improvement to recovery. The word "recovery" is, I know, a very mobile one in medicine, but if there is any need to be more exacting about it in phage-cured dysentery than in other diseases, everything is in favour of the dysentery-cured patient.

As to your statement that in many cases of bacillary dysentery "the infection may be self-limiting" so that "recovery may occur without any specific treatment," I presume you mean here recovery by saline or other purgation treatment. In that case, reference to the third paragraph, p. 274, of my paper will provide a reasonable explanation of the "recovery" of the majority of such cases. In my opinion these cases are mostly phage "cures." Any doubt in regard to this may be dispelled by a persistent examination for the presence of phage of a number of acute dysentery stools—the patients being on no specific treatment whatever—when sooner or later phage will be found appearing among the recovery patients. These, then, are recoveries due to specific phage development. Such investigations underlie the phrase "other considerations," which perhaps escaped you, in the same paragraph.

This leads me to comment also upon the following remarks in your article:—

> "Only rigidly controlled parallel series of treated and non-treated cases will give information of real and lasting value," dysentery being "by no means always a serious and progressive malady." And again, "Since the evidence of the value of this treatment is anyhow not so convincing as to make it inhuman to withhold it from any sufferer, it would be a real service to therapeutics if those who, like Dr. Compton, have access to an unlimited number of cases of bacillary dysentery would treat alternate cases with the *bacteriophage* and the others by any one of the *approval methods* (italics mine), giving in each case a detailed bacteriological examination before and during treatment and chronicalling the clinical course. Only by such an investigation can the question be solved which ten years of scattered observation and uncontrolled reports, suggestive though they may be, have still left unanswered."

What does this mean? Are you here proposing saline treatment versus phage treatment alone or, on the other hand, serum treatment plus saline (a recognised approval method) versus phage alone? That the suggestion is for one of these methods is clear, I think, from your further remarks that in my cases:—

> "The ordinary saline treatment was carried on coincidently with the specific measures. Such a result, taken at its face value, appears to be excellent, but it is a constantly recurring lesson in medicine that face value results are not safe guides to the value of medicaments."

Let us consider the methods that at present hold the field. In the state of our knowledge to-day there appears to me to be fundamentally a choice of three: (1) saline alone; (2) antidysentery serum plus saline; (3) antidysentery bacteriophage plus saline. Saline I have included in all, because this is classical; and with reason; for, whatever lesions the microbes of bacillary dysentery may provoke, it is essential to combat the toxæmia of the disease resulting from the liberated bacterial endotoxins. That, I take it, is the chief raison d'être of sodium sulphate by mouth, or, in the graver cases, physiological saline subcutaneously. Concerning the first of these methods, saline treatment, as there is nothing specific about this, it is obvious that when "cure" results there is reason to suspect the intervention, as already sufficiently insisted upon, of endogenous specific phage; d'Herelle has suggested that the origin of such phage may be symbiotically contaminated coliform bacilli. As concerns the second method, serum therapy, saline is always prescribed as a means of keeping the large bowel well flushed out and thus combating toxæmia. Yet does not the antiserum itself contain endotoxin neutralising antibodies? It is supposed to. Surely, then, if any specific treatment might lend itself to dispense with coincident saline treatment it would be this. But it does not. Why then, coming to the third method, should the patient not have the benefit of saline treatment also when phage therapy is adopted? Here I consider salines by mouth more than ever necessary, at least initially, because the attack of the phage on the offending bacilli means, theoretically at least, the liberation of endotoxin in relatively important amounts.

In view of all this, I am bound to consider your suggestion in regard to "controlled parallel series," treating "alternate cases with the bacteriophage and the others by any one of the approval methods," as entirely beside the point. Present-day knowledge in no way justifies such an experiment.

I am, Sir, yours faithfully,
Alexandria, August 23rd, 1929. A. COMPTON.

SUBJECTIVE PHENOMENA AND COLOUR VISION.

To the Editor of THE LANCET.

SIR,—All visual phenomena are subjective as is well realised by the physiologist and medical man. For instance, if all men and women were totally colour-blind there would be no such thing as colour or if everyone, like a percentage of men, saw only three colours in the spectrum red, green, and violet there would be no such colour as yellow. In a recent book a well-known physicist makes the following statement, "When we are dealing with something definite and tangible such as a colour," but a colour is not definite and tangible. Again, many physicists treat the old theories of colour vision as if they were demonstrations in mathematics—that is, any set of facts is put into mathematical form in correspondence with the theory. If another set of facts be taken an entirely different mathematical arrangement is given. Each mathematical arrangement may be correct but both cannot be true, any more than a man could have his left ear absent, deformed, and normal all at the same time.

The visual phenomena to be described are seen best as soon after awaking in the morning as possible. If the reader find that he cannot immediately see any of the phenomena described or even fail after repeated trials—though this is not at all likely—he should select one of the most intelligent men or women of his acquaintance, and having described the conditions of the experiment, without giving any clue to the phenomena to be observed, ask his friend what he sees in the requisite conditions. When his friend has described the phenomena which follow he will probably have no difficulty in seeing them himself. If on awaking in the morning the reader will look at a window or windows, preferably more than one, then immediately close his eyes and cover them with a pillow, he will see a very clear-cut positive after-image of the windows and adjacent wall. All the light parts will be light and the dark parts dark. If the eyes be kept quite still it will be noticed that the light parts gradually approach the centre of the field of vision and finally disappear with a movement exactly like that of a whirlpool. If, however, when the eyes have been covered they be moved rapidly from side to side the central dark parts of the after-image will be obliterated and the light parts form themselves into a light blur. Now this experiment is very significant, it proves conclusively that the photo-chemical stimulus in vision is movable in the retina. The cause of this movement is undoubtedly the contraction of the muscles of the eye causing unequal pressure on different portions of the retina.

Now observe the effect of moving material on the centre of the retina. On opening one eye on awaking in the morning and looking at the ceiling the central portion is seen as an irregular, circular, rhomboidal, or star-shaped black spot. On closing the eye again a bluish-violet circle appears at the periphery or middle of the field of vision, contracts, and then after breaking up into a star-shaped figure and becoming brighter disappears, to be followed by another contracting circle. If the eye be opened when the star figure has formed in the centre it will appear as a bright rose-coloured star, much brighter than any other part of the field of vision. If, however, we wait till the star has broken up and disappeared before opening the eye, it will be found that only a black spot is seen in the centre. Helmholtz, though he saw the foveal region, sometimes dark and sometimes bright, states that he was never able to reproduce the latter condition voluntarily though the above shows how it may be done, and that he could not explain the facts. This experiment shows conclusively that the foveal region is sensitised from the periphery.

Currents seen in the field of vision are not due to the circulation. These currents may be seen in numerous ways. The following is an easy method of seeing them. If one eye be partially covered with an opaque disc, whilst both eyes are directed forwards in a not too brightly illuminated room and special attention be paid to the covered eye an appearance of whirling currents will be seen with this eye. These currents appear to be directed towards the centre, and have a very similar appearance to a whirlpool. On closing both eyes all the portion in which the whirling currents are seen appears as dull purple. These currents cannot be due to blood-vessels, because we know that the centre of the retina, corresponding to the point where the greatest movement is seen, is free from vessels. The appearance is also very different from that of the movement of blood in vessels. The experiment succeeds best if the eyes have been previously exposed to a fairly bright light. An opaque disc in a spectacle frame suffices admirably, a certain amount of light being allowed to enter the eye from the periphery. Ferree[1] finds, and I agree with him, that the streams carry with them the visual quality, colour, and brightness of the background from which they come. Ferree considers that eye movement is the chief or sole factor in the formation and direction of these currents, but I see them quite clearly with my eye quite still, and the whirling in the centre is not appreciably different when the eye is moved from one point to another. The masterly paper by Ferree should be read by anyone interested in the subject of vision. The illustrations are very good.

Numerous other subjective phenomena have been described by me[2] and by Purkinje, and all the facts strongly support the theory of vision which I gave in 1889—namely, that the cones are the sole terminal perceptive elements, the rods being concerned with the formation and distribution of the visual purple. Apart from the numerous facts against the duplicity theory, which supposes that the rods are percipient elements for perception in a dim light, it will be found that it is supported almost entirely by misstatements—namely (1) that certain animals have only cones and others have only rods; (2) that the periphery of the retina is colour-blind; (3) that the eye is totally colour-blind in dark adaptation; (4) that the Purkinje phenomenon and the recurrent image are not found with the fovea.

With regard to these I offer the following criticisms. (1) Though I have examined numerous collections I have never been able to find any animal with only rods or only cones, neither have I found anyone who has seen such a retina. The tortoise is the most quoted; it is stated to have only cones. The rods and cones in the retina of the tortoise are as clearly defined and distinct as in the human retina.

---

[1] Amer. Jour. Psychol., 1908, 484.
[2] The Physiology of Vision, London, 1920.

(2) The periphery of the retina is not colour-blind, when colours of sufficient intensity are used. The reader can test this for himself with a doctor's red lamp. He will find he can see it as red to the extreme periphery.

(3) In dark adaptation the eye is not totally colour-blind. Further, there is no scotoma or blind area corresponding to the rod-free portion of the macula which is equal to a visual angle of about three degrees.

(4) The Purkinje phenomena and recurrent image are found with the fovea. Hess showed not only that the recurrent image was found with the fovea, but also that it was bent outwards at this region as it would be if the visual purple had to flow into the fovea. Helmholtz and Nagel stated that there was no evidence that the rods were percipient elements.

This letter summarises a communication read last July before the Association Française pour l'Avancement des Sciences at their Congress in Havre, and will, I hope, interest a medical audience.

I am, Sir, yours faithfully,
F. W. EDRIDGE-GREEN,
Special Examiner and Adviser to the Board of Trade on Colour Vision and Eyesight.
Willesden Green, August 12th, 1929.

DISINFECTANT PACKETS.

To the Editor of THE LANCET.

SIR,—In the report of the meeting of the fourth Imperial Social Hygiene Congress in your issue of July 20th (p. 140) you quote Mrs. Rolfe as having given certain figures "for what they were worth." May I suggest that their value is not greater than zero? The statistical genius which sets five army corps with a gonorrhœal incidence-rate of 18·70 per 1000 as a control to five army corps with an incidence-rate of 10·92 per 1000 does not deserve to be noticed, and the phrase, "difference in favour of the men not provided with packets," whether yours or Mrs. Rolfe's, can be based on nothing but desire.

I am, Sir, yours faithfully.
J. ROSSLYN EARP.
Denver, Colorado, August 16th, 1929.

Obituary.

EDWARD ERSKINE HENDERSON, M.B. CAMB., F.R.C.S. ENG.

THE sudden death of Edward Henderson occurred while on a fishing holiday in Ireland. The eldest son of the late Dr. Edward Henderson of Shanghai, Edward Erskine Henderson was born in China in 1870. He was educated at Harrow, St. John's College, Cambridge, and Guy's Hospital. Having taken the M.B. in 1895, he was house surgeon at Guy's to Mr. Golding Bird, and obstetric assistant to Dr. Peter Horrocks. On leaving Guy's he married and went out to join his father's firm, but he did not stay long in the East. While there, he held the post of assistant surgeon to the Shanghai Hospital. He came home in 1898 and began working for the F.R.C.S. He was also enrolled as a student at Moorfields Hospital, working with Sir John Tweedy and Mr. William Lang, and later with Mr. Lang and Mr. Lawford. He was clinical assistant at Moorfields for 15 years. For many years he held the post of ophthalmic surgeon to the Queen Mary's Hospital for the East End and was at one time assistant surgeon to the South London Ophthalmic Hospital, but increasing deafness spoiled his chances of other appointments, and professionally he was best known as an efficient editor of ophthalmic journals. He joined the editorial staff of the *Ophthalmic Review* in 1909 and in the next year was chosen editor; he carried this journal through critical times until it was amalgamated with the Royal London Ophthalmic Hospital *Reports* and the *Ophthalmoscope* in the *British Journal of Ophthalmology* in 1917. He was sub-editor to the late Sydney Stephenson till 1923 and editor in-chief thence onward till his death. With Prof. E. H. Starling he was the author of a valuable research on the factors which determine the formation of the intraocular fluid; and he assisted the late R. H. Clarke in the latter's experimental work on the minute anatomy of the central nervous system.

Henderson was a most versatile man; his manipulative dexterity showed itself not only in operations but in the beautiful work in wood and ivory which he did on the lathe. He was a good sportsman in every sense of the word; a first-class shot with the pistol, he competed regularly at Bisley in the years before the war. He was well read, and disliked colloquialism and slang. His eldest son was killed in battle in 1918. Much sympathy will be felt with his widow and children in their bereavement.

RAPHAEL BELILIOS, M.D., F.R.C.S. EDIN.

THE death occurred on June 19th, at Shanghai, of Dr. Raphael Belilios, from complications following an operation for an acute appendicitis.

Born in 1873, Dr. Belilios was the elder son of the late A. R. Belilios, J.P., and received his medical education at Edinburgh, where he graduated M.B., Ch.B., in 1901. He later took the M.D. with honours and the D.T.M. (Lond.) and became F.R.C.S. Edin. After a short period of practice at Muswell Hill while continuing his special study of the eye, Dr. Belilios emigrated to Hong-Kong where he soon established a large general practice. He held appointments as lecturer and examiner in anatomy and physiology in the Hong-Kong School of Medicine. Deciding to devote himself entirely to ophthalmology, he moved to Shanghai in 1912 and became one of the foremost authorities on the eye in the Far East, his reputation extending to Europe. Patients from all parts of China came to Shanghai to consult him, while Eastern potentates sent escorts for him when they required his services. Dr. Belilios became lecturer and later professor of ophthalmology in the St. John's University of Shanghai and ophthalmic surgeon to St. Luke's Hospital. On the arrival of the British Defence Force in 1927 he was appointed consulting oculist to the corps.

Dr. B. H. S. Aylward, Port Health Officer, Woosing, Shanghai, writes: "I first met Belilios in 1897 at Edinburgh, when he was reading for his second professional, and we soon became close friends. He and his wife who survives him lived near to the Royal Infirmary, and many were the pleasant evenings his circle of close friends spent there. His wife was an accomplished musician, and used to encourage us in our attempts to sing grand opera. Belilios himself had a pleasant tenor voice. He was a keen fisherman, but his principal hobby was conjuring, at which he was expert; possibly the training of his hand by conjuring at Edinburgh had something to do with his dexterity as an operator. Belilios was the most generous of men, in word and deed. He was a brilliant worker and never lost his enthusiasm."

THOMAS WILLIAM BUCKLEY, M.D. DURH., M.R.C.S. ENG.

Dr. T. W. Buckley, who died on August 8th, was born at Betley, Staffs, in 1859. He received his medical education at St. Thomas's Hospital and Owens College, and qualified L.S.A. in 1882, and M.R.C.S. Eng. in 1883. He took the M.D. of Durham University in 1900. He acted for a time as assistant to his uncle, Dr. Thomas Morton, and later was assistant house surgeon at the Staffordshire County Infirmary and surgeon on one of the vessels of the Ocean S.S. Company. In 1888 he bought a practice at Thrapston, Northants, and in partnership with the late Dr. J. W. Gainer, worked over a huge rural district for 20 years. He was M.O.H. of the district and J.P. for Northamptonshire. On the outbreak of war, Dr. Buckley immediately volunteered for service abroad. Refused at first on account of his age, he received a commission in 1915, and was sent to a military hospital at Shoreham. In 1915, having been promoted to the rank of major, he acted for a year as Assistant Commandant and Officer Commanding the R.A.M.C. detachment at Princess Christian Military Hospital, Englefield Green. In 1916 he was appointed to No. 2 Special Medical Board, Caxton Hall, ultimately becoming its President. The work was very heavy, involving visits of inspection to hospitals in and round London, and many hours of writing reports, as well as the routine work of the Board. Dr. Buckley was not demobilised till 1919, and never quite recovered from the strain of the war years. He spent the rest of his life very quietly in the little village of Clopton, a few miles from the centre of his old practice. Fond of reading and of country life, he was never at a loss for occupation. Dr. Buckley was modest about his own attainments, which were considerable. He had a keen sense of humour, and could tell many interesting stories of his experiences. He leaves a widow, son, and two daughters, one of the latter being a medical woman.

Medical News.

SOCIETY OF APOTHECARIES OF LONDON.—At recent examinations the following candidates satisfied the examiners in the undermentioned subjects :—

Surgery.—P. S. Balachandran, Middlesex Hosp.; K. C. Bhattacharyya, Calcutta and St. Thomas's Hosp.; A. Clark, Glasgow and London Hosp.; R. J. Kagan, St. Mary's Hosp.; N. H. Kettlewell, Bristol; J. M. Lees, Guy's Hosp.; J. E. Moody, St. Mary's Hosp.; C. Parthasarthe, Birmingham; A. Somerville, Sheffield; and A. W. B. Wiggins, Sheffield.

Medicine.—K. C. Bhattacharyya, Calcutta and St. Thomas's Hosp.; P. D. Kapur, Glasgow; N. H. Kettlewell, Bristol; H. H. Lakin, Birmingham and London Hosp.; J. M. Lees, Guy's Hosp.; A. Liberis, St. Bartholomew's Hosp.; W. McDermott, London Hosp.; R. Norrie, St. Andrew's; E. J. O'Loughlin, Birmingham; and A. W. Tam, Singapore.

Forensic Medicine.—K. C. Bhattacharyya, Calcutta and St. Thomas's Hosp.; W. T. Ellis, Charing Cross Hosp.; B. L. Fishout, Cardiff and Manchester; W. M. Hamer, Manchester and Charing Cross Hosp.; J. M. Lees, Guy's Hosp.; C. A. Munro, Glasgow; E. J. O'Loughlin, Birmingham; and S. Ramadas, St. George's Hosp.

Midwifery.—J. Britanischski, Berlin and London Hosp.; R. Gilmore, Manchester; W. St. A. Hendricks, St. Mary's Hosp.; C. Hortop and J. M. Lees, Guy's Hosp.; A. R. Madden, St. Mary's Hosp.; A. Somerville, Sheffield; and F. A. Yarde, St. Mary's Hosp.

The Diploma of the Society was granted to the following Candidates, entitling them to practise medicine, surgery, and midwifery: B. L. Fishout, N. H. Kettlewell, H. H. Lakin, J. M. Lees, C. Parthasarthe, and A. W. Tam.

INDUSTRIAL WELFARE SOCIETY.—At the tenth annual lecture conference to be held at Balliol College, Oxford, from Sept. 13th to 17th, the afternoon session on Monday will be devoted to industrial health. Dame Louise McIlroy will address a special session for women at which Dr. Margaret Hossell will preside, and Dr. D. A. Coles will take the chair at a special session for men on Health Problems in Industry. On the previous Sunday evening Mr. D. R. Wilson is lecturing on Fatigue Research and its Practical Application in the Factory.

ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN.—This institution, which has its out-patient department in Leicester-square, and receives in-patients at 202, Uxbridge-road, last year treated 214 in-patients, whose average stay was 42 days, and 10,528 new out-patients. The annual report records that the receipts from donations fell by £100, following a fall of £600 in the previous year, and the Board of Management express "grave fears" for the future unless larger financial help is forthcoming. There were 2180 laboratory examinations and 875 patients were treated in the X ray department.

TRELOAR CRIPPLES' HOSPITAL.—The Alton hospital, founded by Sir William Treloar, comes of age this month, and there is to be a dinner at the London Mansion House on Oct. 22nd to celebrate the occasion. The opportunity will be taken to make an appeal for £100,000, the estimated cost of new buildings. The present buildings are the wooden structures of the Princess Louise Military Hospital, erected for the wounded in the South African war, and now worn out. The trustees find that the cost of repair and maintenance exceeds the interest on the cost of rebuilding. The hospital was originally designed for 200 patients; and to-day at Alton and Hayling Island the number of crippled children under treatment is 405.

SOCIETY FOR THE STUDY OF INEBRIETY.—The thirteenth Norman Kerr Memorial Lecture will be delivered by Sir Josiah Stamp, G.B.E., LL.D., D.Sc., on Tuesday, Oct. 8th, at 4 P.M., in the Great Hall of the B.M.A. House, Tavistock-Square, London, W.C.1., the subject being Alcohol as an Economic Factor.

CASTLEFORD, NORMANTON AND DISTRICT HOSPITAL.—On August 23rd Princess Mary opened this new hospital which has been built at a cost of £42,000.

HOSPITAL DINNERS.—The annual old students' dinner of St. Bartholomew's Hospital will be held in the Great Hall of the Hospital on Tuesday, Oct. 1st, at 7 for 7.30 P.M., Sir Frederick Andrewes in the chair.—The annual dinner of St. George's Hospital Medical School will take place on the same day, 7.15 for 7.45 P.M., at the Hyde Park Hotel, Knightsbridge, when Mr. D. Cotes-Preedy, K.C., will preside.

WESTMINSTER OPHTHALMIC HOSPITAL.—According to the annual report, the new hospital, which was opened exactly a year ago, "is far from being completely equipped, and is not yet in full working order." At the end of the year only 42 beds contained in two wards had been opened. Henceforward a much larger income will be needed to meet an expenditure which must necessarily increase considerably, and the committee appeal for a revenue of £20,000 a year.

YORKSHIRE HOSPITALS AND MOTORING ACCIDENTS. The *Yorkshire Evening Post* publishes the results of an inquiry into the cost and the degree of pressure upon the hospitals of that county caused by motoring accidents. In the first six months of the present year 660 victims of such casualties were treated at Leeds Infirmary, of whom 252 were admitted. They cost £1977, of which £170 was repaid by patients; £75 of this was a thank-offering from one patient. Last year Bradford Infirmary received £24 towards the £1174 spent upon 137 in- and 220 out-patients. In the year ended in April last some 600 cases were treated in the casualty ward of Hull Royal Infirmary, and 125 in-patients cost £931, of which £85 was repaid. The annual report of Doncaster Royal Infirmary states that last year 3808 casualty patients were treated, and that the wards are so constantly filled with motoring accident cases that it is impossible to deal with the long waiting list of local persons requiring operations.

METROPOLITAN DISTRICT NURSING ASSOCIATION.—This institution employs 19 trained nurses for the sick poor of Central London, who last year paid over 50,000 visits and, in addition, saw nearly 40,000 patients at clinics, dispensaries, and treatment centres in Westminster, Finsbury, Holborn, and St. Pancras. During the severe epidemic of measles in the spring 440 cases of that disease were referred to the Association, of which more than one-half had complications requiring skilled nursing; only five of these acute cases died. The 144 maternity cases all did well. The Association, which was founded by Florence Nightingale and others in 1875, last year spent £3160 of an income of £3930.

QUEEN CHARLOTTE'S MATERNITY HOSPITAL.—On Tuesday in last week the first sod was cut for the new buildings that are to be erected in Goldhawk-road, Hammersmith. Provision is being made for 358 beds, but the isolation block is to be erected first, with 30 beds for cases of puerperal sepsis, a disease for the investigation of which a special laboratory is being provided, with a staff of bacteriologists, doctors, and nurses placed in a house adapted for the purpose and connected by a covered way with the isolation block. Princess Mary is to lay the foundation-stone on Nov. 4th, but the removal from Marylebone-road will be gradual, since the present 80 beds will be more than quadrupled when the scheme is complete and the money available. The beginning is being made with the money raised by the National Mother-saving Campaign launched by the hospital two years ago. The site has some fine trees which, as far as possible, are being preserved.

DONATIONS AND BEQUESTS.—Dr. Robert Hamilton, of Leeds-road, Harrogate, left over £3000 to charities, including £250 each to the Bradford Royal Infirmary, the Bradford Children's Hospital, the Bradford Royal Eye and Ear Hospital, the District Nursing Association; and £200 each to Dr. Barnardo's Homes, the National Children's Institution, and the Bradford Institution for the Blind. The testator also gave £100 each to Harrogate Infirmary, Harrogate Hospital, Harrogate Home for Incurables, the Royal Medical College, Epsom, Victoria Children's Convalescent Fund, Royal Albert Asylum, Lancaster, and four other institutions.—Mr. Emile John Frank Hardenberg, M.R.C.S., L.R.C.P., of Frederick-road, Chingford, left £2500 to the London Orphan School, Watford, and £1000 to Guy's Hospital.

Appointments.

EDMOND, HENRY, M.B. Birm., D.P.H., has been appointed Tuberculosis Officer for Wigan.

UNDERWOOD, E. A., M.B., Ch.B.Glasg., D.P.H., Deputy Medical Officer of Health for Rotherham.

Certifying Surgeons under the Factory and Workshop Acts: BOOTH, W. N., M.B., B.S.Durh. (Harlow and Parndon District of Essex); EVANS, J. P., L.R.C.P. Lond., M.R.C.S., (Colwyn Bay); and SUNDERLAND, E. B., L.R.C.P. Lond., M.R.C.S. (Haverhill District of Suffolk).

Vacancies.

further information refer to the advertisement columns.

ock Hospital, Connaught-road, E.—M.O. At rate of £110.

ts' Hospital, 91, Finchley-road, N.W.—Jun. H.S. Also st. H.S. At rate of £150 and £100 respectively.

o, Manchester, Crossley Maternity Hospital.—Half-time M.O. at rate of £50.

nder-Lyne District Infirmary.—H.S. At rate of £150.

ely Hospital.—2 H.S.'s. Each at rate of £150.

Carnarvonshire and Anglesey Infirmary.—H.S. £200.

al United Hospital.—H.S. At rate of £150.

on Urban District Council.—Part-time Asst. M.O. £325.

al General Hospital.—Cas. S. £100.

m and Midland Eye Hospital, Church-street.—H.S.

Ear and Throat Hospital.—Third H.S. At rate of

and East Lancashire Royal Infirmary.—Res. H.P. Also 4th H.S. £130.

Hospital, Wandsworth Common, S.W.—H.S. At rate

gh Hospital, Derby-road.—Hon. Laryngologist and Also Jun. M.O. At rate of £125.

al Eye and Ear Hospital.—Jun. H.S. £120.

al Hospital.—H.S. to Special Departments. At rate

Royal Victoria and West Hants Hospital.—Two Each at rate of £120.

—H.S. At rate of £150.

enbrooke's Hospital.—Res. Anæsthetist. At rate Also H.P. and H.S. Each at rate of £130.

pworth Village Settlement.—H.P. At rate of

Throat, Nose, and Ear Hospital, Gray's Inn-road, n. Chief Clinical Assts.

ness Tuberculosis Colony, Barrowmore Hall, Great Asst. M.O. £250.

al West Sussex Hospital.—Hon. Asst. Orthopædic

Maternity Hospital, City-road, E.C.—Asst. Res. ate of £80.

Ophthalmic and Aural Hospital.—Aural 200.

thing Hospital.—H.S. At rate of £100.

cil.—Asst. County M.O.H. £750.

Greenwich-road, S.E.—H.P. At rate of

Hospital.—H.P., H.S., and Asst. H.S. 0.

monton, N.—2nd Asst. S. £500.

Nottingham General Hospital.—H.P. Also 2nd Cas. O. Each at rate of £150.

Otago and Dunedin University Hospital, New Zealand.—Sen. Res. M.O. £500.

Princess Louise Kensington Hospital for Children, North Kensington.—Hon. Radiologist.

Queen Charlotte's Maternity Hospital, Marylebone-road, N.W.—Res. Anæsthetist. At rate of £80.

Radcliffe-on-Trent, Notts County Mental Hospital.—Jun. Asst. M.O. £350.

Rotherham Hospital.—H.S. £180.

Royal Chest Hospital, City-road, E.C.—Res. M.O. At rate of £150 Also Out-patient M.O. and H.P. Each at rate of £100.

Royal National Orthopædic Hospital, 243, Great Portland-street, W.—H.S. £150.

Royal National Orthopædic Hospital, Country Branch, Middlesex—H.S. £150.

Southampton, Royal South Hants and Southampton Hospital.—Jun. H.S. Also Cas. O. At rate of £130 and £120 respectively.

Talgarth, Breconshire, South Wales Sanatorium.—Sen. Asst. M.O. £350.

Torquay, Torbay Hospital.—H.P. £175.

Walsall General Hospital.—Res. Surg. O. At rate of £200.

Watford, Herts, Peace Memorial Hospital.—Res. M.O. At rate of £150.

West London Hospital, Hammersmith.—One H.P.; two H.S.'s; one Aural and Ophthalmic H.S.'s; Res. Asst. Cas. O., Males; also Res. Asst. Surg.

Weston-super-Mare General Hospital.—Res. H.S. £130.

The Chief Inspector of Factories announces a vacant appointment for a Certifying Factory Surgeon at Tunbridge Wells (Kent).

Births, Marriages, and Deaths.

BIRTHS.

BRADFORD.—On August 28th, at Goodrington, South Devon, the wife of Ernest Cordley Bradford, M.A., M.B., B.Chir. Camb., of Laneside, Horsham, Sussex, of a son.

LEAKEY.—On August 21st, at Toro, Uganda, the wife of R. A. B. Leakey, L.R.C.P., L.R.C.S. Edin., L.R.F.P.S. Glasg., of a son.

OLDERSHAW.—On Sept. 3rd, at 15, Weymouth-street, Portland-place, W.1., to Olive, wife of Martin Oldershaw, M.D. Lond., F.R.C.S. Eng.—a son.

SAVEGE.—On August 24th, at a nursing home, Stonehaven, N.B., the wife of Major J. M. Savege, R.A.M.C., M.B., Ch.B. Aberd., of a daughter.

MARRIAGES.

BARNES—BERTHON.—On August 25th, at the Subdeanery Church, Chichester, John Francis Lorel Barnes, M.R.C.S. Eng., L.R.C.P. Lond., of Thame, Oxon., to Anna Etheldreda Margaret, only daughter of the late Captain Leonard Berthon, 9th Royal Warwicks Regt., and Mrs. Berthon, of Selsey, Sussex.

MURRAY—THOMAS.—On August 27th, at Holy Trinity Church, Exmouth, John Douglas Ridout Murray, M.B., B.Chir., F.R.C.S., to Evelyn Leslie (Mollie), only daughter of Mr. and Mrs. Lewis Thomas, of Chessington, Exmouth.

TOWNEND—WEST.—On August 24th, at St. Peter's Church, South Croydon, Roy D. M. Townend, M.R.C.S. Eng., L.R.C.P. Lond., to Eleanor L. Clayton, M.R.C.S. Eng., L.R.C.P. Lond., only daughter of Mr. and Mrs. William West, of South Croydon.

DEATHS.

BELL.—On August 16th, quite suddenly, at his residence, Dogflud, Farnham, Surrey, Dr. William Ker Bell (Captain, R.A.M.C.), formerly of Shaldon, South Devon.

CAREY.—On August 29th, suddenly, at Church-square, Basingstoke, Frank Russell Carey, L.D.S. R.C.S. Eng.

HENDERSON.—On August 23rd, at Belleek, Ireland, Edward Erskine Henderson, M.B., B.Ch. Camb., F.R.C.S., of Thackham, Hartley Wintney, Hants.

KISCH.—On August 27th, at Westbourne-terrace, W., Albert Kisch, M.R.C.S. Eng., L.S.A., aged 86.

MACKINNON.—On Tuesday, August 20th, at Davaar, Cirencester, Charles MacKinnon, M.A., M.B., C.M., aged 71.

MORGAN.—On August 26th, Jerome William Morgan, L.R.C.P.I., L.R.C.S.I., L.M., Lieut.-Colonel, A.M.S. (retired), aged 85.

PATTERSON.—On August 31st, in London, Robert Lloyd Patterson, L.R.C.P., L.R.C.S. Edin., L.R.F.P.S. Glasg., of Castle-street, Hereford.

POWELL.—On August 31st, at Brighton, after an operation for appendicitis, Walter Erichsen Powell, M.R.C.S., L.R.C.P., aged 34.

WOOLLATT.—On August 13th, the result of an accident near St. Malo, Percy Charles Woollatt, M.D., F.R.C.S., aged 51.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

JEAN PAUL MARAT.

THE value of submitting persons famed in history to the illuminating scrutiny of trained psychologists is now accepted. Many facts which previously baffled the historian are thus made clear, and the true factors which underly the policies of princes, statesmen, and nations are brought to light. It does not follow that theories based on evidence surveyed at long range are necessarily correct, but that insight into the reason for abnormal conduct is more likely to be reached by those who have experience in assessing them. We welcome, therefore, a study of the life of Jean Paul Marat, from the standpoint of a psychiatrist physician. Dr. Charles W. Burr, of Philadelphia (Annals of Medical History, 1929). Marat was born in 1743 and murdered by Charlotte Corday in 1793 at the age of 50 years. Little is known about his family history, and our only picture of his childhood is painted in Marat's own reminiscences, which are histrionic and bombastic in the extreme. Marat, according to himself, was an ideal youth with a passion for fame, an exceptional education, and a horror of injustice and oppression. He describes himself as "reflective at fifteen and a thinker at twenty-one." Dr. Burr justly remarks that such sentences suggest the illusions of memory which are so pronounced a feature of paranoid personalities. About the age of 17 Marat left home with the idea of becoming a physician. He studied at Toulouse, Bordeaux, Paris, and London. In 1765 or thereabouts he started to practice medicine in Church-street, London, where he remained for about 12 years. In 1775 he was granted a medical doctorate by the University of St. Andrews. During his residence in London he commenced writing. Among his works were "An Essay on the Human Soul," the "Discoveries of M. Marat on Fire, Electricity and Light," and an "Essay on Gleets"—he claimed to be able to cure any case of gleet. In the "Essay on the Human Soul" Marat concludes that the meninges were the seat of the soul; and the organs of thought, memory, and will. A political book entitled the "Chains of Slavery" was published by him in 1774; in this work "the clandestine and villainous attempts of princes to ruin liberty are pointed out and the dreadful scenes of despotism disclosed." There was some difficulty in getting the book published, and Marat developed ideas of persecution and conspiracy for he decided that the English Government wished to prevent the circulation of the book. He therefore "disappeared" to Holland and turned up almost at once in the North of England, where he paid a round of visits to certain patriotic societies. The style in which this book is written, together with Marat's curious conduct certainly suggest paranoid trends of thought. The work abounds in phrases beloved of the eccentric demagogues who still flourish at the Marble Arch, and who declaim against tyranny, despotism, the sins of the rich, and the guilt of kings. It is probable that Marat's pages did receive some notice from authority, but there is no evidence to substantiate his fears of personal violence or the necessity for flight. Dr. Burr rightly insists that such beliefs and conduct suggest to a psychiatrist delusional ideas on the part of Marat.

Leaving England in 1777 Marat became physician to the Garde du Corps in the household of the Comte d'Artois. There followed a period in which he wrote much on scientific subjects. Dr. Burr tells us that none of these writings possess any particular merit, but Marat himself thought very highly of them. Again we have evidence of ideas of persecution. Marat felt that his work was decried by "envious cowards," and we hear of him proclaiming that the envious philosophers of France successfully prevented the publication of one of his works. From his post as physician to the Artois household Marat came to practice medicine in Paris, urged to do so, he tells us, "by the many sick persons who were despaired of by their physicians and to whom I had restored health." He boasts that his success was prodigious until he excited the envy of the doctors of the Faculty, who, he was convinced, held frequent meetings to consider the best means of slandering him and thus ruining his practice. Again the notion of persecution is followed by a change of occupation, this time to politics and to the editing of a paper, *The Friend of the People*.

There is no need to recite at length the political creed of Marat. The people in his view were those without property or occupation. They alone had the right to govern. His opponents were abused in his writings and speeches in scurrilous and offensive terms. During his last few years Marat led a life of seclusion, constantly fearing attack by his enemies, especially sudden death by assassination or poisoning. These fears were probably not without some justification, but he seems to have become obsessed with feelings of persecution, and lived preaching murder and anarchy as if every man's hand was against him. In 1790 he proposed to the Assembly that "eight hundred gibbets ought to be erected in the Tuileries to hang all traitors," and declared that 270,000 persons would have to suffer death in order to free France from her oppressors. It is of interest that for five or six years before his murder Marat suffered from a skin complaint which caused a painful pruritus. Dr. Burr quotes Dr. Graham Little as holding that the skin lesion was probably a dermatitis herpetiformis. It is known that the itching was relieved by sitting in a bath of hot water, and it was while in his bath that he was murdered.

Dr. Burr sums up the life of Marat as a slowly-growing insanity, in which delusions of suspicion and persecution were prominent from an early age. Towards the close of his years Marat conceived himself as a political genius, with intuitive powers and comprehension. His speeches and writings were prolific, and bear the stamp of egoism and grandiose self-satisfaction. There is much to be said for Dr. Burr's view that Marat was a paranoiac. He was undoubtedly a man of paranoid outlook on life, for he found persecution everywhere, and made the frequent changes of residence and occupation which are often associated with this type of personality. But it is nowhere suggested in Dr. Burr's review that Marat's insanity illustrates the fixed, organised, and systematised delusional state which makes up the paranoia of the text-book descriptions. All will agree to Marat's eccentricity, and to his occasional insane conduct and delusional ideas. There is no need to split hairs over Marat's clinical pigeon hole, but Dr. Burr does not solve the deeper personality problems raised by the life of this paranoid physician and revolutionist.

PAINFUL FIBROSITIC NODULES.

To the Editor of THE LANCET.

SIR,—Is there any satisfactory treatment for the nodules which persist after repeated attacks of fibrositis? My back muscles are studded with them, their cause having been abscessed teeth, long since removed. Most are painless, and beyond being centres of infection are of no account. But one, quite half an inch in length, is so placed in the right trapezius that lying on the right side causes pain which wakens at night, and without sleep a doctor cannot work. I have been at two spas, and the only treatment advised by the specialists, in addition to baths and the waters, has been heavy massage. This is painful and futile.

Can any of your readers report on some of the more modern methods. Is ionisation useful, or high frequency? Has X ray therapy been tried, or radium? I have seen radium dissolve a keloid. Might it not dissolve what is obviously a scar in the fibrous tissue of the muscle? Fibrositic nodules are extremely common. When the cause has been removed surely there must be some satisfactory method of treating them.

I am, Sir, yours faithfully,

August 20th, 1929. M.B., B.CH.

OPHTHALMOLOGY FOR THE LAYMAN.

THE object of a little book recently published[1] is to teach the layman something about the elementary anatomy and physiology of the eye and its more common diseases, in order that he m[illegible] [illegible]operate with the physician in matters of treatment. T[illegible]od chosen is to devote separate chapters to the ail[illegible] [illegible]idental respectively to childhood, adult life, and dis[illegible] giving a brief summary of several diseases and the[illegible] treatment in each chapter. Much of this matter [illegible] have been omitted without loss if greater stress had been [illegible] on those symptoms which point to the necessity of expert advice. Among these are commencing squint in infants, the beginnings of myopia in school-children, headaches at all ages, and failing sight in adults, which may be due to the onset of cataract when delay is harmless, or to a chronic glaucoma when delay is dangerous, or may simply point to the need of glasses. As it stands the book is too much like a very elementary text-book and is not always accurate, for example, in the section on the anatomy and physiology of the retina. It would be better to omit those points which cannot be clearly explained and to concentrate on the subjects likely to prove of practical service. Even in its present form the book will meet the demand of those people who want to know something about the various diseases of the eye with which they are liable to be overtaken or of which they hear in relation to their friends. This demand is quite legitimate though its gratification may occasionally lead to uninstructed criticism rather than to coöperation with the family doctor.

[1] Your Eyes and Their Care. By Edgar S. Thomson, M.D., Surgeon-Director, Manhattan Eye, Ear and Throat Hospital, New York. New York and London: D. Appleton and Co. 1929. Pp. 175. 5s.

THE N.S.P.C.C.

IT comes as a shock to be reminded that 40 years ago no child in the home who had not reached the age of ten years was under the protection of the Crown, and that no one who wronged him could be brought into the presence of the law. It was not until 1889 that the Prevention of Cruelty to and Protection of Children Act was passed, and the Metropolitan and City Police authorities gave instruction that all cases of cruelty to children reported to them should be handed over to the National Society for the Prevention of Cruelty to Children to be dealt with by the Society. Since then much has been done for the emancipation of the child, but the forty-fifth annual report of the N.S.P.C.C. shows that much remains to do. In 1928–29 40,541 cases were reported, under the following headings: neglect and advice sought, 34,362; manslaughter, 1; abandonment, 78; exposure, 455; ill-treatment and assault, 3146; begging, 205; corruption of morals, 316; other wrongs, 1978. These figures show an excess of nearly 1000 cases over the previous year's total, but this is probably due to the wider response of the public to the Society's appeal that cases should be reported to it, and to a wider public knowledge of the Society's object in seeing that every child in the land shall live an endurable life. *It is satisfactory to note that under the heading of* "corruption of morals" the figures for 1928–29 show a reduction, though a small one, of 14 when compared with the figures for 1927–28. Increased confidence in the Society is shown by the fact that there is a notable increase in the number of instances in which parents have sought advice. In the report of the Medical Officer, Dr. L. D. Saunders, emphasis is laid upon the need for after-care where medical treatment has been found necessary. Four more inspectors have been added to the staff during the year. The Society's Central Offices are at Victory House, Leicester-square, London, W.C. 2.

THE TREATMENT OF ECZEMA.

IT is recognised that there are many factors which may help to produce the clinical manifestations called "eczema." They include, for instance, disturbances of the alimentary and endocrine functions, and metabolic disorders, such as gout, obesity, and hyperglycæmia. But the actual cause of the eruption is still obscure, and treatment remains correspondingly empirical.

Of the internal remedies at present in use C. Bruck[1] will find general agreement in condemning arsenic, except in such cases as are anæmic. A similar if less drastic criticism is applicable to yeast, ichthyol, and sulphur, although the waters of certain sulphur spas are sometimes valuable, possibly because of their relief of constipation and hepatic torpor, or by a tendency to counter acidosis. Following Kreibich's work on the nerve relationships of eczema, modern dermatology aims at reducing the excitability of the nervous paths, including the sympathetic, and often does this with some success by intravenous injection of sodium bromide, or, recently, by giving magnesium bromide intramuscularly. In this connexion Bruck finds *the internal administration of antipyrin and pyramidon* useful in acute cases, and he has observed that antipyrin ointments have a soothing effect locally, applied in 5–10 per cent. cum eucerin aqua base. Care must be taken not to apply this ointment over too large an area, although so far no ill-effects from absorption have been noted, even in children.

There is no specific dietary for eczema, but proper regulation of the intake in cases of obesity, gout, and hyperglycæmia is, of course, often beneficial. When the patient is undernourished, the cutaneous condition will sometimes improve if cream and butter in excess of the normal intake are added to the diet. Relative acidosis or alkalosis of the blood suggests possible lines of approach in the neurodermatitis type of eczematous manifestation, and in the exudative diathesis which is associated in some cases. Ehrmann claims successes for treatment of neurodermatitis by giving hydrochloric acid by mouth—a method based on his finding that a relatively large proportion of cases show hypochlorhydria. In children with the exudative diathesis and eczema Scheer recommends acidification of the milk, and good results are sometimes obtainable by adding a solution of 20 c.cm. acid. hydrochlor. dil. in 50–150 c.cm. of distilled water to half a litre of milk. The milk must be scalded and cooled before the weak acid solution is added. In cases of relative acidosis, in which the seborrhœic eczemata can be grouped, small doses of atophan followed by a mixture containing sod. bicar. and mag. carb. ust. seem to assist the local applications.

All in all the bulk of modern opinion favours the view that a combination of treatments gives better results than mere application of the well-tried ointments and lotions.

APPETISING PREPARATIONS.

Messrs. Frank Cooper, Ltd., of Victoria Buildings, Oxford send samples of their "Oxford" marmalade, mint jelly, and horseradish cream. The marmalade, which is well known everywhere, was first made on a small scale from a domestic recipe and had its main consumption in Oxford, but for many years it has been manufactured on a commercial scale in response to wide demand. Made without any objectionable preservatives it has the Seville orange flavour. The firm send samples also of a mint jelly to be used as a substitute for mint sauce, and a horseradish cream made of freshly grown horseradish and real cream. These latter relishes to food are usually liked only by those who also have a very distinct idea of how they should be made, so that to hit off a popular taste will be something of a triumph.

THE "HYGIENIC" LECTURE BOARD.

Dr. S. T. Beggs, Medical Officer of Health for the Borough of Middleton, Manchester, has called our attention to the "Hygienic" Lecture Board, which is intended to take the place of the ordinary blackboard. The writing is done on a paper surface which is rolled up and down on, or from side to side of, the lecture board by means of a hand crank. Obviously this method of exhibiting diagrams and notes is more hygienic than that of the usual blackboard and chalk method, while much time is saved by reason of the fact that the diagrams can be permanently preserved and exhibited as required. The paper is written upon by special black or coloured crayons, which do not soil its surface when rolled and unrolled; it is supplied in lengths of 20 yards by 30 inches wide, on a cardboard tube, and the board can be illuminated by an electric bulb and reflector attached to a flexible arm. The apparatus can be fixed to a wall of the lecture room or used on a portable easel. The makers are Messrs. J. Halden and Co., Ltd., 8, Albert-square, Manchester.

AURAL DISEASE AND BATHING.

IN an annotation on this subject[1] a plugging material was referred to made of wool-fibre and plasticine which is sold by chemists as a satisfactory means of preventing the entry of water into the ear. Messrs. Frank Eyles of 8, Western-road, Brighton, Sussex, have sent us samples of ear plugs manufactured for this purpose, which are very carefully prepared by hand, the long fibred medicated cotton wool being thoroughly amalgamated with the plasticine in order to ensure that no disintegration of the plug occurs when it is being extracted from the ear The plugs serve a useful purpose.

THE PRE-SCHOOL CHILD.

THE thesis set out in a recent addition to the "To-day and to-morrow" series,[2] which already includes more than 80 volumes, is that, under present conditions, the home is not the ideal place, nor are parents the ideal people, for the major part of child-rearing. The smallness of the modern home and the absence of domestic help lead to a situation, especially after the arrival of the first-born, in which man and wife have to seek their pleasures separately, and family life is broken from the start. The effect on the child of limited space and lack of garden is a serious handicap to early activity. Allied to the problem of the cramped house or flat is that "special creation of the present age," the only child, a child upon whom the mother tends to lavish all the love which was meant to be shared by many, with the result that, in Mr. Lewis's telling phrase, "mother love becomes smother love." *The solution proposed* is an extension of nursery schools on a national scale for all classes. Mr. Lewis considers "that the nursery school is as essential to the mental slums of Golders Green as to the more material slums of Deptford." While lauding America for the enthusiasm with which she has set about providing for her pre-school children, he criticises the tendency to use nursery schools as research laboratories. There is no justification, he says, in creating the abnormal to study the abnormal, *neither should the child be sacrificed to make a student's* degree day. The book consists of five chapters and an introduction, such matters as play, discipline, and the duties of parenthood being dealt with in an unusually fresh and stimulating way. Mr. Lewis is happy alike in his matter and his manner, and has produced an informative and readable book.

The Deshell Laboratories, Ltd., manufacturers of Petrolagar, have changed the name of their company to Petrolagar Laboratories, Ltd., but have not changed their management or address.

A Contribution
TO THE STUDY OF THE MATERNAL DEATH-RATE.

BY G. F. GIBBERD, M.S. LOND., F.R.C.S. ENG.,
OBSTETRIC REGISTRAR, GUY'S HOSPITAL.

THIS study is based on a comparison of the midwifery in the Guy's Hospital Maternity District as it is to-day and as it was 60 years ago. We know fairly accurately how midwifery was done at Guy's in the days of Galabin and Braxton Hicks. We know how much (or how little) attention was then paid to the prevention of sepsis. We know that there was never any antenatal work. We are fortunate in having an accurate and detailed analysis of the cases that were delivered under these conditions, with a full account of the results obtained. By comparing these results with those of the present day upon a similar group of patients, living under similar conditions, in roughly the same area, and knowing accurately, as we do, the modern methods in use, we may get some valuable information as to how far recent changes in practice have benefited the modern mother. Further, we may discover the faults still to be remedied in our efforts to reduce the present mortality-rate.

MIDWIFERY AT GUY'S IN 1870.

The following account is copied from the report by Galabin published in Guy's Hospital Reports in 1876.[1]

> The district . . . lies within a radius of about a mile from the hospital, and patients are attended at their own homes by the students. A certain number of these, who have already attended a course of lectures on midwifery, are appointed extern obstetric attendants for each month. They reside close to the hospital, and are expected to abstain from visiting the post-mortem and dissecting rooms while they are attending midwifery cases. Two senior students, who have obtained a legal qualification to practise, are appointed resident obstetric assistants and hold office each for one month as junior and one month as senior. They live within the walls of the hospital, and are ready at all times to assist the junior students. The assistant obstetric physician is sent for to superintend all cases in which any obstetric operation is performed.

In the 12 years from October, 1863, to September, 1875, the total number of women delivered was 23,501. There were 106 fatal cases, giving a maternal mortality-rate of 4·4 per 1000. If this figure is compared with the present-day mortality-rate for the country as a whole, we might conclude that the "advances" in midwifery during recent years have led to no decrease in the dangers associated with childbirth. But such a conclusion is not necessarily true, since the comparison is unfair. A much more comparable series is that of the 21,423 "district" cases delivered in the ten years 1910 to 1928 inclusive. This number includes all cases domiciled in the Guy's Hospital district and delivered by the hospital, whether the actual delivery took place in the patient's own home or in hospital. It is difficult to obtain figures of an average practice carried out by a hospital service, since if only patients delivered on the district are considered there will be an unduly low incidence of abnormalities, because the majority of difficult cases will not be delivered in their own homes. If, on the other hand, only patients delivered in hospital are considered, there will, of course, be an undue proportion of difficult cases. By grouping patients according to the area in which they are ordinarily resident we can to some extent eliminate selection. Since the Guy's Hospital district is comparatively small and served by the hospital largely to the exclusion of other practitioners and institutions, these 21,423 district cases can be taken as a fairly representative sample of the general population, in which factors tending to selection have been to a great extent overcome. The only patients excluded are those who were ordinarily resident outside the geographical area of the maternity district.

The 21,423 cases under consideration therefore form a group of average women, as nearly as possible comparable to the group of 23,501 women delivered between 1863 and 1875. In this group (1910–18) there were 22 maternal deaths, giving a maternal mortality-rate of 1·03 per 1000. Thus the maternal mortality-rate in the practice of the Guy's Hospital maternity district during the past ten years is about one-quarter what it was 60 years ago, and this in spite of the fact that obstetric interference is now very much more common. Unfortunately there are no detailed analyses available for recent years before 1928 of the various obstetric abnormalities and operations, but the practice in the Guy's Hospital maternity district has changed but little in the last ten years, and an analysis of the 1670 cases delivered in 1928 may be taken as representing fairly accurately the methods in use during the 1919–28 period.

OBSTETRIC INTERFERENCE.

The following table shows how much more frequently major obstetric interference is resorted to now than it was 60 years ago. The figures for the 1863–75 period have been compiled from Galabin's report published in 1876.[1] The figures for 1928 have been obtained from the Report of the Maternity Department of Guy's Hospital for 1928.[2]

Table I. shows the percentage of cases in which interference was resorted to.

TABLE I.

Nature of operation.	12 years 1863–1875.	Year 1928.
	Per cent.	Per cent.
Forceps	0·51	4·6
Version	0·45	0·3
Craniotomy..	0·07	0·18
Cæsarean section	Nil.	1·3
Manual removal of placenta ..	0·32	0·18
Instrumental induction of labour	Nil.	2·4
Total obstetric interference ..	1·35	8·86

It is very unlikely that the enormous increase in obstetric interference can be due to any comparable increase in the incidence of obstetric abnormalities. The only possible explanation for the striking difference is that to-day interference is considered proper where formerly it was not. In 1928 the proportion of Cæsarean sections to total deliveries was as great as the proportion of all obstetric operations to total deliveries 60 years ago; in spite of this craniotomy was performed twice as frequently in 1928 as in the former period. Moreover, the forceps rate is now nearly ten times what it was in 1870, and version (which in the days of Galabin and Braxton Hicks was a relatively common method of delivery in difficult cases) is only slightly less common in the present day practice of Guy's Hospital.

What is the meaning of this change in our methods? It is sometimes explained on the grounds of modern impatience and meddlesomeness. If only the obstetrician, it is sometimes said, would exercise his patience more and his art less, natural delivery would be a much more common event, and natural delivery must be the best thing for the patient. This line of reasoning generally concludes with the aphorism that the best way to reduce the frequency of the tragedies of labour is to leave to Nature what Nature ordained. Such an argument has been used so often, and when applied to indiscriminate interference is so obviously true that we must not be carried away by its extreme application. To say feebly that we are not impatient and meddlesome is an assertion that we cannot expect to be accepted without proof; but, in so far as such a thing is capable of proof, we have some statistical evidence in a comparison of the frequency with which the placenta was removed manually. This operation is sometimes, but only rarely, an absolute necessity, and the frequency with which it is performed may be to some extent an index of the impatience and meddlesomeness of the obstetrician, since it is not performed out of consideration for any physical suffering on the part of the patient. In 1870, during a time when interference generally was far less frequent than it is to-day, the placenta was removed manually almost twice as often as it is to-day. This at least suggests that midwifery now is conducted with no less patience than it was 60 years ago.

[1] Report of Guy's Hospital Lying-in Charity, Guy's Hospital Reports, 1876, xxi. (3rd Series), 285.

[2] Clinical Report of Maternity Department, ibid., 1929, lxxix. 277.

There can therefore be only one explanation for the increase in obstetric interference, and that is that our standards of what we regard as "tolerable suffering" have changed since Galabin's time. This is a natural consequence of changes in social conditions in the same period. These two changes go hand in hand, and to condemn the one as a curse, while accepting the other as a blessing, is merely a peevish outcry against the inevitable. The increase in obstetric interference has come to stay, just as our improvements in the standard of living have come to stay, and any attempt to tackle the problem of maternal mortality by "back to Nature" methods is doomed to fail at its very inception—doomed by the impossibility of forcing it upon our patients, rather than by any unwillingness on the part of the accoucheur. Even if it could be adopted it still remains to be shown that it would result in any reduction in the mortality-rate. The figures quoted show that in multiplying the frequency of interference by six, we have divided the maternal death-rate by four, but it does not follow that by doubling the present interference rate we should again halve the mortality-rate. We must find the amount of interference that will give the minimum mortality. The general outcry against obstetric interference is certainly justified when that interference is excessive, but we must not expect—indeed we cannot wish—that it should be so seldom resorted to as it was 60 years ago. The solution to the problem of maternal mortality will not come from drastic changes in the accepted modern technique of conducting labour. Indeed, the present technique and the present-day willingness to interfere are the result of true advances in the practice of obstetrics, a response to the demands of women to be relieved of some of the intolerable suffering to which they were submitted three generations ago. With them come, not an increased mortality, but a death-rate reduced to one-quarter of the original figure.

AVOIDABLE COMPLICATIONS.

The part played by antenatal work in reducing the mortality is difficult to assess, but an index of its value can be obtained by comparing, in the two series, the number of deaths which follow complications that can be avoided by efficient antenatal work. The most important are: *(a)* disproportion, *(b)* malpresentation, *(c)* toxæmias of pregnancy, and *(d)* serious intercurrent diseases. The deaths ultimately due to these causes have been set out in Table II.

Disproportion is now responsible for far less deaths than formerly, and this improvement must be due, in part at least, to the fact that antenatal supervision has forewarned us and enabled us to deal more safely with such cases. Part of the improvement is, of course, due to improved technique—for example, the substitution of Cæsarean section for a difficult craniotomy—but even so, Cæsarean section is safe only in so far as it has been foreseen at the antenatal clinic and performed before it has become a dangerous operation late in labour. Malpresentation was ultimately responsible for only about half as many maternal deaths as it was 60 years ago, and here again antenatal care must be held responsible for the improvement. Comparative figures on the toxæmias of pregnancy are notoriously fallacious, since the frequency and severity of eclampsia seems to vary within wide limits in different places, and also possibly in different periods, but in spite of this the reduction in the death-rate from eclampsia in the more recent series is probably significant, and can be taken as still further proof of the value of antenatal work. Apart from fulminating cases, which sometimes occur quite soon after examination has revealed a normal blood pressure and urine, there is no doubt that antenatal care, if efficiently carried out, can greatly reduce the incidence of eclampsia.

TABLE II.—*Death-rates per 1000 Deliveries in Cases of Disproportion, Malpresentation, Toxæmia, and Intercurrent Disease.*

1863–1875 (23,591 cases).		1919–1928 (21,423 cases).	
Disproportion—		Disproportion—	
Forceps	5	Cæsarean section	3
Version	2	Craniotomy ..	1
Craniotomy ..	6		4 = 0·19*
Ruptured uterus	5		
	18 = 0·76*		
Malpresentation—		Malpresentation—	
Version	1	Ruptured uterus	1 = 0·046*
Ruptured uterus	1		
	2 = 0·08*		
Eclampsia	7 = 0·29*	Eclampsia	1
		Other toxæmias ..	2
			3 = 0·14*
Intercurrent diseases—		Intercurrent diseases—	
Phthisis	1	Phthisis	1
Heart disease ..	5	Heart disease ..	3
Tumour of brain	1	Hyperthyroidism	1
Purpura	1		
	8 = 0·32*		5 = 0·24*

* Per 1000.

There can be no doubt that the care of the general health during pregnancy forms a very important part of antenatal supervision, and although no very [illegible] decrease in the number of deaths from intercurrent [illegible] be demonstrated in these series, the benefits of antenatal care in this direction are probably far greater than analysis seems to suggest. *The fact remains, however, that where pregnancy* complicates, or is complicated by, some serious intercurrent disease which of itself is likely to cause death, antenatal care has not been rewarded by any very great decrease in the death-rate.

SEPSIS.

The part played in the reduction of maternal mortality by changes in our outlook on sepsis during the last 60 years is well brought out in Table III.

TABLE III.—*Death-rates per 1000 Deliveries from Sepsis.*

1863–1875 (23,591 cases).		1919–1928 (21,423 cases).	
Sepsis following normal labour	26	Sepsis following normal labour	1 = 0·046*
Sepsis following P.P.H.	6		
	32 = 1·31*

Version, malpresentation ..	3	Cæsarean section	2 = 0·09*
Version, placenta prævia	1		
Forceps	1		
Craniotomy ..	3		
Manual removal of placenta ..	2		
	10 = 0·42*		
Total deaths from sepsis ..	42 = 1·73*		3 = 0·14*

* Per 1000.

In studying the death-rate from sepsis it is important to distinguish between spontaneous deliveries in which sepsis supervened and cases where the infection followed major obstetric interference. The factors contributing to infection in these two groups are probably different, and an estimate of the efficacy with which the various factors have been dealt during recent years can best be obtained by considering each group separately.

In natural delivery, trauma and perhaps also direct inoculation by the hands of the attendant are probably not the most important factors predisposing to the sepsis. If we try to find some explanation for the fact that the death-rate from sepsis following natural delivery was 30 times as great in the 1863–75 series as in the 1919–28 series, we are tempted to attribute it to more efficient prevention of cross infection in recent years. In the present practice of Guy's Hospital, isolation of "district" cases is comparatively easy, since patients with pyrexia are effectively isolated in their own homes and, if admission to hospital is thought necessary, the patient is taken into the septic ward, which is situated in a block of buildings far removed from the maternity ward. The student who has delivered such a patient is easily suspended from duty if necessary and has not, as a rule, been in contact with more than one or two patients before his case of sepsis has become manifest. Thus, except for these one or two contacts, isolation is efficient even before the first manifestation of sepsis. The danger of cross infection is, however, less easily dealt with among ward cases, but here again it is only very rarely that an infected case—i.e., a patient in whom repeated attempts at delivery have been made outside the hospital—is admitted. Such a patient is potentially infected and is therefore a potential danger to all the other patients in the hospital ward, and the danger is all the more insidious in that she may show no signs of her infection until a day or two after she has mixed with other patients in the ward. At Guy's Hospital the majority of patients who live outside the "district" and who are delivered in the hospital have been looked after during pregnancy by the hospital. Emergencies from outside practitioners are seldom admitted. This limitation of the hospital service is more than compensated for by the relative freedom from serious sepsis in the maternity ward.

The attitude taken towards isolation 60 years ago can be judged from the following extract from Galabin's report of 1876.

> . . . it is satisfactory to record that there is no instance in which contagion seemed to have been communicated by the attendant from one patient to another. It is usual to suspend an extern from his duties for a few days if symptoms occur in any patient attended by him which are thought to indicate any special risk of infection. In the case of the resident obstetric assistants, who are not generally in such close attendance upon the patients, reliance is placed upon antiseptic ablutions and change of clothing. The nearest approach to an epidemic was in November and December, 1874, when there were four deaths from puerperal septicæmia among patients delivered within four weeks. All four, however, were attended by different gentlemen, and no communication whatever could be traced between them.

It is seen that the precautions then, although not so strict as those of to-day, were nevertheless on the same general lines. It is true that nowadays four deaths from septicæmia in four weeks would be regarded as more than an "approach to an epidemic," and the more searching inquiries that would be made to-day would probably have revealed some common contact. But the extract from Galabin's report is quoted to show that he was fully alive to the importance of the principle of isolation, and we must assume that his ideas were as faithfully carried out as are similar (though more stringent) ideas to-day. Thus, while there has been an enormous decrease since 1870 in the number of deaths from sepsis following natural delivery, it is difficult to attribute all this improvement to more efficient isolation of contacts, since the broad principles of isolation were enforced 60 years ago. The influence of trauma and of gross contamination at the time of delivery should not be very different in the two series, since we are dealing only with natural deliveries.

The one factor that is different in the two series is the general condition of the mother. With antenatal care, as a rule, the general health of the average mother is probably far better to-day than it was in Galabin's time. The opportunities that we now have of ensuring proper and sufficient food and adequate general treatment are far greater than in former years. Furthermore, in Galabin's report a delivery is classed as natural so long as it was not effected by version, forceps, or craniotomy, and many cases under this heading must have been exhausted by a labour so prolonged as to leave the patient quite unfit to deal with an infection even of low virulence. It has already been pointed out that the forceps rate is now ten times what it was 60 years ago and, so far from causing an increased death-rate from sepsis, it seems quite likely that this very interference is responsible for the decrease, because it has saved many women from the exhaustion that would have followed a more prolonged labour ending in a "natural" delivery. Increased obstetric interference carried out with proper regard to the principles of asepsis and antisepsis may be regarded as a large factor in the reduction of the septic death-rate in the 1919–28 series.

The relative safety attendant upon present-day obstetric interference is further borne out by reference to the septic deaths in cases where the delivery was not spontaneous. In spite of the increased frequency of interference in the 1919–28 series there was a very great reduction in the deaths in this group. This improvement is partly due to the fact that severe trauma after obstetric operations is far less common to-day than formerly, since difficult craniotomies and high forceps deliveries are avoided wherever possible by the induction of premature labour or by Cæsarean section. The greatest factor, however, in rendering obstetric interference relatively safe must be the changes in operative technique. In the light of the results recorded here it would seem safe to conclude that so long as the facilities for good aseptic and antiseptic technique are available and are fully used, the modern tendency to increase the amount of obstetric interference is not merely justifiable but definitely beneficial.

ANTEPARTUM AND POSTPARTUM HÆMORRHAGE.

Modern practice has carried with it practically no decrease in the death-rate from accidental hæmorrhage. In all the fatal cases in the 1919–28 series (Table IV.) the hæmorrhage was of the concealed type. Three of the patients were delivered by Cæsarean section, and in one the condition was treated by plugging the vagina.

TABLE IV.—*Death-rates per 1000 Deliveries in Cases of Antepartum Hæmorrhage.*

—	1863–1875 (23,591 cases).	1919–1928 (21,423 cases).
Accidental hæmorrhage	5 = 0·21 per 1000	4 = 0·19 per 1000
Placenta prævia ..	6 = 0·25 "	2 = 0·09 "

The relatively large number of deaths from this cause may be taken as an indictment against the method of treatment adopted at Guy's Hospital, and, although no fixed line of treatment can be said to be practised, Cæsarean section has been performed frequently in the more serious cases of concealed accidental hæmorrhage during recent years. This can hardly, however, be held responsible for the unfortunate results, since they were roughly the same in Galabin's series, in which more conservative measures were invariably taken. The difficulty is that the fatal result is frequently due to an associated toxæmia of great severity and often of sudden onset. The modern methods of treating blood loss by transfusion are so effective that it is disappointing to find no improvement where these methods have been employed. The reason is probably that patients with concealed accidental hæmorrhage die nowadays not so much from hæmorrhage (which can be treated effectively) as from profound toxæmia. This belief is born out by clinical experience and by post-mortem findings.

The death-rate from placenta prævia shows a definite improvement in the recent series. This is partly due to the fact that antenatal supervision has at times enabled us to detect, or at least to suspect, the condition before the patient has been weakened by a serious hæmorrhage, but most of the improvement is probably attributable to our improved methods of combating blood loss.

Postpartum hæmorrhage now very rarely causes death, as is shown in Table V.

TABLE V.—*Death-rate per 1000 Deliveries from Postpartum Hæmorrhage.*

1863–1875 (23,501 cases).	
Postpartum hæmorrhage	12
Syncope after slight hæmorrhage	1
Inversion of uterus with hæmorrhage ..	1
Total	14 = 0·59 per 1000
1919–1928 (21,423 cases).	
Spontaneous rupture of uterus with hæmorrhage	1
Inversion of uterus with hæmorrhage ..	1
Total	2 = 0·09 per 1000

This very striking improvement affords still further evidence of the valuable help given by modern methods of treating hæmorrhage.

CONCLUSIONS.

Two series of cases have been compared with reference to the maternal mortality-rate. The difference between the two series is mainly that the one is an example of midwifery practice 60 years ago, and the other of modern practice. In all other respects the two groups are as nearly as possible identical, and any differences between them are to be attributed to inevitable changes in social conditions. By limiting the cases to patients domiciled in a compact "district," the distortion usually present in "in-patient" figures has been eliminated, and by including all cases who, though domiciled in the "district," were nevertheless delivered in hospital, the distortion usually present in "out-patient" figures has also been avoided. The series can, therefore, be regarded as a fair average sample of the general population, at least among the particular social class exemplified by the residents in the Guy's Hospital "district."

The maternal mortality-rate in the last 60 years has fallen from 4·4 per 1000 to 1·03 per 1000, and this improvement can be traced directly to changes in obstetric methods. These changes in practice have resulted in an increase in the amount of interference, but even so the total interference rate at the present time is less than 9 per cent. It is contended that the increased interference up to this point is justified by the results obtained and that it may be an important factor in diminishing the death-rate by eliminating those cases of profound obstetric exhaustion that must have occurred 60 years ago. It is to our improved aseptic and antiseptic technique that we must attribute the fact that, in spite of the much greater frequency of interference, the danger of subsequent sepsis has been very much reduced. Amongst cases of spontaneous labour the conscientious use of a simple antiseptic technique and strict attention to the principles of isolation have practically abolished sepsis as a cause of death.

Antenatal care has shown its value most dramatically in reducing the death-rate in cases of disproportion and malpresentation, and also in making eclampsia a rare disease. But it has done more than this: it has given us the opportunity to look after the general health of the patient during pregnancy so that she is better able to face the risks of labour and the puerperium.

The use of intravenous saline or gum saline or of blood transfusion has contributed largely to the reduction in the death-rate from postpartum hæmorrhage and placenta prævia, but concealed accidental hæmorrhage accounts for practically as many deaths as it did in former years, and the cause of death in these cases seems to be a profound toxæmia which we cannot treat. In spite of the enormous amount of study that has been spent on the toxæmias of pregnancy since Galabin's time our treatment for this condition, once it has developed (whether in association with accidental hæmorrhage or as eclampsia), is as ineffective as ever it was. Apart from the experience gained from periodical swings of the pendulum from radical to conservative lines of treatment we have nothing of fundamental importance to add to the treatment of 60 years ago. We have succeeded in preventing eclampsia to a great extent, but we must not therefore imagine that we have advanced in our treatment of the condition once it has arisen. Under present conditions of practice an occasional case of fulminating eclampsia or of concealed accidental hæmorrhage will occur in spite of reasonable antenatal care, and it is in the treatment of such cases that modern methods have proved so disappointing. To prevent a disease is certainly better than to treat it, but until we can prevent every case of severe toxæmia there is still a real need for efficient treatment.

The death-rate from intercurrent diseases was 0·32 per 1000 in the 1863–75 series, and 0·24 per 1000 in the 1919–28 series, showing that antenatal care has been unable greatly to benefit the pregnant woman who is already seriously ill with some other disease. This is to be expected, since in these cases we cannot look upon childbearing as anything more than a contributory factor in causing death, and we cannot expect antenatal treatment to cure the primary disease. The close approximation of the figures in the two groups is interesting in view of the question of the reliability of national mortality figures. How far do such figures include deaths from intercurrent disease? It is suggested that 0·3 per 1000 may be taken as a true measure of the deaths from non-obstetrical causes in an average unselected practice, and if this is so it is obvious that these cases become a serious factor only when the total mortality-rate is very low.

Investigations

INTO THE

BLASTOGENIC PRINCIPLE IN FOWL SARCOMA,

AND THEIR SIGNIFICANCE IN THE THEORY OF THE ORIGIN OF MALIGNANT TUMOURS.

BY ERNST FRÄNKEL, M.D.,
THE UNIVERSITY INSTITUTE FOR CANCER RESEARCH, CHARITÉ HOSPITAL, BERLIN.

BETWEEN 1926 and 1929 I published a series of papers [1] [2] [3] describing some investigations on Peyton Rous's fowl sarcoma These were undertaken with the support of the German Central Committee for Cancer Research and the Fund in Aid of German Science.* My first investigations were based on the work of Gye and Barnard [4] [5] whose technique I learned in London, and on the assumption of Rous and Murphy [6] that these tumours are caused by a filtrable virus. The Rous fowl sarcoma is now admitted to be a true malignant tumour both morphologically and pathologically. As is well known, it differs from other malignant tumours since it is possible to produce tumours of the same kind in healthy fowls by means of filtrates alone, without the inoculation of cells. A single injection of 1·0 c.cm. of a sterile and cell-free Berkefeld filtrate into the pectoral muscle of a healthy *fowl produces tumours which appear microscopically* to be true tumours; they infiltrate the healthy tissue without causing any great inflammatory reaction, and give rise to typical metastases in other organs, such as the lungs, liver, and heart.

---

* I am particularly indebted to Prof. M. Busch of the State Department of Health, who supervised the pathological and anatomical part of the work and prepared microscopic and macroscopic sections.

The fact that the filtrate now and again contains a cell has recently been made by Teutschländer, Nakahara, and other authors[8] [9] a reason for believing that the tumours might be caused by isolated cells or parts of cells injected with the filtrate. I have succeeded, however, in proving that tumours can be evoked by the injection of counted cell suspensions containing a relatively large number of cells, but not by suspensions containing a small number. When a suspension containing only a few cells (for example 4000–10,000) is injected into the breast of a fowl on both sides, on one side by itself and on the other with an unheated cell-free filtrate or one that has been heated to 50° C. for a quarter of an hour, a tumour appears only on the side on which the filtrate was injected. The same result followed the injection of the filtrate without the suspension. This proves that the tumour could not have been produced by isolated cells in the filtrate.

I arrived at the same conclusion as a result of some experiments which I undertook to see whether tumours could be produced by injecting the blood, spleen, and egg-yolk of tumour-bearing birds, in many of which there was no histological evidence of metastasis in the organ from which the injected substance was taken, or indeed in any part of the body. My findings agree with those of Rous and Murphy, Bürger, Busch, Pentimalli,[10] Llambias and Brachetto Brian.

I have also investigated the question of whether or not Gye and Barnard are right in assuming that the cause of the Rous sarcoma is an unspecific "virus," together with a chemical "specific factor." The results which I obtained agree with those of Harkins, Schamberg, Kollmer, Kast, Flu, Sternberg, and others, and show that the "specific factor," a chloroform-killed filtrate, is alone responsible. The various attempts which have been made to cultivate the virus, with all kinds of aerobic and anaerobic cultures, have been uniformly unsuccessful. Nevertheless, a Rous tumour has twice been produced with suspensions cultivated in bouillon at 37° C. and then rapidly centrifuged, even in weak dilution. This dilution contained some ordinary Gram-positive rod-shaped organisms which I believe to have adsorbed the activating principle of the *tumour into their* outer surfaces. Fujinami and Inamoto report a similar observation in which the organisms were staphylococci, and which is especially interesting in view of the occasional success of Blumenthal and his colleagues in cultivating tumour-activating microbes from human cancers.

Chemical Experiments.

After my failure to cultivate the virus I turned my attention more along chemical lines. It is possible by precipitating the euglobulin with carbon dioxide to divide the diluted filtrate into two fractions. By analogy with complement-splitting, I describe the one as the euglobulin fraction, and the other, less accurately, as the albumin fraction. I obtained four positive results with the globulin fractions of various filtrates, and only two with the albumin. Baker and McIntosh, Harde,[11] Sugiura,[12] and Benedict have also worked along these lines, have established that the pH value of the agent never rises above 10·0 nor falls below 3·8, that acid filtrates are less effective than alkaline, and that the time taken by a filtrate to act depends upon the quantity of the agent present. Trypsin stimulated growth (Baker and McIntosh), a fact which suggests that fermentative processes underlie the generation of Rous sarcoma. Sugiura and Benedict, who precipitated the globulin with ammonium sulphate, could produce tumours only with the globulin fraction, and found practically all the nitrogen content of the filtrate in the precipitated globulin. In conformity with Teutschlander and *the other workers quoted, we found that 50°–52° C.* was the critical temperature for the efficiency of the filtrate, and also that the time factor and the efficacy of the injected substance depended very largely upon its quantity. I therefore proceeded systematically to investigate the fermentative nature and chemico-physical properties of the "agent," and to test for it and demonstrate its existence by the current methods. The carbon dioxide introduced to precipitate the globulin had already been proved innocuous, and it was now demonstrated that a tumour could be produced after chlorine had been passed through the filtrate. Seven filtrates through which hydrogen had been passed and eight through which oxygen had been passed yielded three and one positive results respectively on inoculation. The fact that it was more effective under anaerobic than aerobic conditions showed in this respect a close analogy to Warburg's anaerobic glycolysis.

I then attempted to isolate the agent by adsorption, the possibility of which had been suggested by my own experiments in the transmission of bacteria, by those of Pentimalli on the transmission of healthy embryonic cells, and by those of Carrell on normal macrophages. I therefore tried to isolate the ferment by Willstätter's well-known method, using variously charged adsorbents. In these experiments I was admirably assisted by Dr. Ernst Mislowitzer, of the Chemical Branch of the Pathological Institute, who placed his great experience in this field unreservedly at my disposal. Acting on his advice, we chose casein as the mildest of all the adsorbents. Adsorption was demonstrated by inoculation tests in six out of thirteen filtrates. On animal charcoal it occurred twice in five attempts, and on infusorial earth and kaolin three times out of five. Since the work was completed we have learnt that Lewis and Andervont[14] in America and Sebastiano[15] in Turin have also reported on adsorption experiments with organic and inorganic adsorbents. These authors attempt to explain their findings from the bacteriological aspect by drawing an analogy with the adsorption of various kinds of true filtrable virus. Believing, however, that the agent is like a ferment, we followed Willstätter's method and tried to isolate the blastogenic principle by washing it out of the adsorbent with phosphates on aluminium hydroxide, succeeding in six attempts out of ten.

It appeared to me that in order to form a correct opinion of the nature of the agent, it was necessary to *estimate its size. The adsorption experiments* had shown that a filtrate was often rendered ineffective by filtration through candles on account of adsorption; I therefore used gauged de Haen filters, membrane filters and "ultrafilters" (Bechhold's collodion filter). In these experiments the agent passed twice out of eight times through a medium membrane filter gauged to pass bacteria, and once out of seven times through a fine one. The inoculation test was positive, however, even after filtration, both through a rapid and a medium ultrafilter, the times being one to five and ten to fifty minutes respectively. The medium ultrafilter holds back benzopurpurin, but passes albumin; and the largest pores will let through particles of about 10 μμ diameter. Finer filters, such as the fine ultrafilter with a time of 100–500 minutes, and the finest ultrafilter have, however, not yet passed the blastogenic principle, so that its size must be about that of the albumin molecule. These filtration tests indicate that it is less likely to be a living virus than a chemical substance. Their results therefore confirm and amplify those of the adsorption and "elution" experiments.

Discussion.

There remains to be considered the application of these results to tumour research as a whole. The Rous fowl sarcoma is the only malignant tumour yet discovered that can be transmitted with certainty by means of cell-free filtrates. It is probable, however, that a number of other mammalian tumours are capable of cell-free transmission. Blumenthal and his colleagues have succeeded in producing tumours in normal animals by injecting the spleen or blood of tumour-bearing rats and mice, and similar results have been achieved by Rhoda Erdmann with filtrates of Jensen's rat tumour. Kritchewski produced a tumour in a rat by injecting substance from a human melanotic sarcoma, and transmitted the tumour by means of sand filtrates and cystic fluid containing blood. None of these results, however, can yet be reproduced with anything like the same certainty and regularity as the cell-free transmission of Rous's fowl sarcoma, which is the only tumour of which the active principle can yet be separated with certainty from the cells. Most of the authorities who have worked with Rous's sarcoma have abandoned the view that the agent is a living virus. The belief in a virus which can lead of its own accord to the growth of a specific malignant tumour when introduced once into the body runs counter to the experience of all clinical and pathological research on tumours. On the contrary, clinical experience of tumours proves with certainty that they can be initiated in the human body by the following stimuli:—

1. Thermal—e.g., cancer of the abdominal skin caused by the "kangri."
2. Physical—e.g., cancer of the skin after X ray and radium applications.
3. Mechanical—e.g., traumatic sarcoma.
4. Chemical—e.g., aniline and paraffin cancer and the pulmonary lympho-sarcoma of the Schneeberg cobalt miners.
5. Parasitic—e.g., cancer of the bladder, due to bilharziasis; cancer of the tongue following syphilitic leucoplakia; and probably cancer of the gall-bladder and ducts in chronic streptococcal infection and cholelithiasis.

Experimental and animal pathology have also provided numerous examples of these various possible causes of malignant tumours. Briefly, a few of the best known are the spiropteric cancer of the stomach in rats, discovered by Fibiger; carcinoma following "kalkbein" of fowls; the production by Yamagiwa and his colleagues of carcinoma in mice by painting with tar over long periods, and the production of cancer in rats and in the ears of rabbits, and on fowls by Choldin; tumours produced with scarlet red by B. Fischer—and the results of inoculation or cell culture, combined with applications of tar and arsenious acid, reported by Carrell and Albert Fischer.

All these examples prove that malignant tumours can be evoked by the most varied causes. It is surely a mere complication to assume the existence of a second exogenous factor, such as a living virus, in addition to all this host of other causes. What we do not know, however, is the nature of the internal process which makes the malignant tumour grow in normal tissue or out of it. If we have succeeded in making it probable that the blastogenic principle isolated from the tumours of fowl sarcoma is not a living virus but a chemical agent or a ferment, it becomes possible to find a place for these tumours in the general theoretical fabric of neoplasmology. Up to the present, this is the only tumour in which the blastogenic principle has indubitably been isolated from the cells. Further research will doubtless be directed towards confirming these results and ascertaining whether they hold good for other malignant tumours. If, by the use of these or other methods, we can discover the nature of the chemicals or ferments which can be isolated from the growths and which stimulate the cells to tumour formation, we may find out that principle of the cause and development of tumours which underlies all the multifarious exciting factors.

Summary.

The tumour-producing agent ("blastogenic principle") of Rous fowl sarcoma filtrates can be separated from the tumour cells and isolated by the usual methods of ferment isolation.

A chemical or ferment theory of the "blastogenic principle" harmonises better with the facts of clinical and experimental investigation than does the hypothesis of a living virus.

DIAGNOSTIC VALUE OF THE ESTIMATION OF BLOOD CHOLESTEROL IN CHOLELITHIASIS.

BY R. H. O. B. ROBINSON, M.B. CAMB.,
F.R.C.S. ENG.,
SURGEON TO OUT-PATIENTS, ST. THOMAS'S HOSPITAL; ASSISTANT SURGEON TO CITY OF LONDON HOSPITAL FOR HEART AND LUNGS; SOMETIME RESEARCH SCHOLAR,
ST. THOMAS'S MEDICAL SCHOOL.

THIS investigation was undertaken to assess the diagnostic value of an estimation of the amount of cholesterol in the blood in cases of supposed cholelithiasis. Before investigating patients known to be suffering from this condition it is obviously essential to decide what can be considered as normal, and to define the limits of the normal, especially as there is considerable variation in the figures given by different authorities both for the mean value and the range of value.

In selecting a method for determining the amount of cholesterol one was chosen in which the quantity of blood withdrawn from the patient was large enough to ensure accuracy, but not so large that one or more withdrawals might impair the general condition, and was, comparatively speaking, easily and quickly carried out. The method was that advocated by Myers in his book,[1] and described originally in papers by Gorham and Myers,[2] and Myers and Wardell.[3] It had the disadvantage of being colorimetric and, therefore, open to an inevitable margin of error.

The estimation is carried out after obtaining the Liebermann-Burchard reaction for cholesterol in the fluid to be estimated. The only absolute method of estimating cholesterol is the gravimetric method of Windaus, after precipitation of the cholesterol in combination with digitonin. It is costly and tedious, and requires larger quantities of blood than are practicable in clinical work. Colorimetric estimation of cholesterol after obtaining the Salkowski reaction has no advantage over the other colorimetric method. For Myers' method 1 c.cm. of blood or serum is required, and a calculation is made to determine the number of grammes of cholesterol per 100 c.cm.

The figures for normal subjects given by various workers using different methods are as follows:—

Autenreith and Funk,[4] in a classical paper upon which much subsequent work has been based, give a normal range in whole blood of 0·140–0·160. They estimate against a standard green colour in an Autenreith comparator after obtaining the Liebermann reaction in the unknown. They hint that, as the method is a colorimetric one, it can only be considered accurate to the second place of decimals. Hanes,[5] using a very similar method, gives for serum a range of 0·110–0·183 with an average of 0·148. Grigaud,[6] estimating four normals, gives for whole blood 0·160–0·165 and for plasma 0·168–0·175, and Chauffard, Laroche, and Grigaud[7] for whole blood 0·160–0·180. Bacmeister and Havers[8] give for whole blood 0·110–0·180. Bloor,[9] using a special method of extraction, gives values for whole blood of 0·190–0·260, and for plasma of 0·170–0·240. Most other workers regard these figures as definitely too high. Gorham and Myers,[2] extracting dried blood, found a range of 0·180–0·190, with an average for 14 cases of 0·150. All these workers were using the Liebermann colour reaction. Weston and Kent,[10] using the Salkowski reaction, give a range of 0·117–0·297, with an average for 52 subjects of 0·182. Gardner,[11] using the digitonin method, gives for serum an average of 0·169 in 48 subjects.

In determining the values for blood or plasma three or four estimations were carried out on each specimen, necessitating the withdrawal of from 8 to 6 c.cm of blood. Considerable discrepancies were found, and certain modifications were introduced into the method. Similar unsatisfactory results obtained by Myers's method have been recorded by Ling.[12] The stages of the method were investigated and the following conclusions reached. It appeared to be immaterial whether the mixing of the blood or serum with plaster-of-Paris was carried out roughly with a glass rod or intimately in a pestle and mortar. After extraction for half an hour, it was still possible in many cases by further extraction to find remaining cholesterol capable of estimation, and it was found necessary to extract for one and a half hours.

The amounts of reacting substances were doubled, but the proportions kept unchanged. As there was considerable evolution of heat during the reaction, the mixture was stirred with a glass rod first until the vigour of the reaction had subsided, and then further mixed by inversion.

Determination was carried out in a colorimeter having cups with fused glass bottoms. This is essential, as the acid chloroform mixture destroys the cement used in the ordinary type of cup. For each estimation ten readings were taken.

In this manner an appreciable time was taken over one determination, and it was found that the intensity of the colour was increasing progressively. Investigation was made, therefore, on the rate of development of the intensity of colour in a standard solution of pure cholesterol after addition of acetic anhydride and pure sulphuric acid compared against a stable standard solution of naphthol green. It was found that it takes 45 minutes for the maximum intensity to develop.

This is a very important point, and one to which insufficient attention has been directed. Myers advises reading after ten minutes, but it is of interest to note that Grigaud[13] states that half an hour is the ideal time, while Autenreith and Funk advise 20 minutes.[4] The rate of development shows no variation within the ordinary range of room temperature, and this accords with the findings of the rate of development of the Salkowski reaction as recorded by Weston and Kent.[10] Bright sunlight should be avoided, but it is unnecessary to keep the reagents in the dark.

In subsequent work a standard solution of cholesterol was always used, as solutions of naphthol green have a yellow-green tinge, as opposed to the blue-green of the Liebermann reaction, and make matching of the colour very difficult. The reaction given by pure

that a number of other mammalian tumours are capable of cell-free transmission. Blumenthal and his colleagues have succeeded in producing tumours in normal animals by injecting the spleen or blood of tumour-bearing rats and mice, and similar results have been achieved by Rhoda Erdmann with filtrates of Jensen's rat tumour. Kritchewski produced a tumour in a rat by injecting substance from a human melanotic sarcoma, and transmitted the tumour by means of sand filtrates and cystic fluid containing blood. None of these results, however, can yet be reproduced with anything like the same certainty and regularity as the cell-free transmission of Rous's fowl sarcoma, which is the only tumour of which the active principle can yet be separated with certainty from the cells. Most of the authorities who have worked with Rous's sarcoma have abandoned the view that the agent is a living virus. The belief in a virus which can lead of its own accord to the growth of a specific malignant tumour when introduced once into the body runs counter to the experience of all clinical and pathological research on tumours. On the contrary, clinical experience of tumours proves with certainty that they can be initiated in the human body by the following stimuli :—

1. Thermal—e.g., cancer of the abdominal skin caused by the "kangri."
2. Physical—e.g., cancer of the skin after X ray and radium applications.
3. Mechanical—e.g., traumatic sarcoma.
4. Chemical—e.g., aniline and paraffin cancer and the pulmonary lympho-sarcoma of the Schneeberg cobalt miners.
5. *Parasitic—e.g., cancer of the bladder, due to bilharziasis*; cancer of the tongue following syphilitic leucoplakia; and probably cancer of the gall-bladder and ducts in chronic streptococcal infection and cholelithiasis.

Experimental and animal pathology have also provided numerous examples of these various possible causes of malignant tumours. Briefly, a few of the best known are the spiropteric cancer of the stomach in rats, discovered by Fibiger; carcinoma following "kalkbein" of fowls; the production by Yamagiwa and his colleagues of carcinoma in mice by painting with tar over long periods, and the production of cancer in rats and in the ears of rabbits, and on fowls by Choldin; tumours produced with scarlet red by B. Fischer—and the results of inoculation or cell culture, combined with applications of tar and arsenious acid, reported by Carrell and Albert Fischer.

All these examples prove that malignant tumours can be evoked by the most varied causes. It is surely a mere complication to assume the existence of a second exogenous factor, such as a living virus, in addition to all this host of other causes. What we do not know, however, is the nature of the internal process which makes the malignant tumour grow in normal tissue or out of it. If we have succeeded in making it probable that the blastogenic principle isolated from the tumours of fowl sarcoma is not a living virus but a chemical agent or a ferment, it becomes possible to find a place for these tumours in the general theoretical fabric of neoplasmology. Up to the present, this is the only tumour in which the blastogenic principle has indubitably been isolated from the cells. Further research will doubtless be directed towards confirming these results and ascertaining whether they hold good for other malignant tumours. If, by the use of these or other methods, we can discover the nature of the chemicals or ferments which can be isolated from the growths and which stimulate the cells to tumour formation, we may find out that principle of the cause and development of tumours which underlies all the multifarious exciting factors.

Summary.

The tumour-producing agent ("blastogenic principle") of Rous fowl sarcoma filtrates can be separated from the tumour cells and isolated by the usual methods of ferment isolation.

A chemical or ferment theory of the "blastogenic principle" harmonises better with the facts of clinical and experimental investigation than does the hypothesis of a living virus.

DIAGNOSTIC VALUE OF THE ESTIMATION OF

BLOOD CHOLESTEROL IN CHOLELITHIASIS.

BY R. H. O. B. ROBINSON, M.B. CAMB., F.R.C.S. ENG.,

SURGEON TO OUT-PATIENTS, ST. THOMAS'S HOSPITAL; ASSISTANT SURGEON TO CITY OF LONDON HOSPITAL FOR HEART AND LUNGS; SOMETIME RESEARCH SCHOLAR, ST. THOMAS'S MEDICAL SCHOOL.

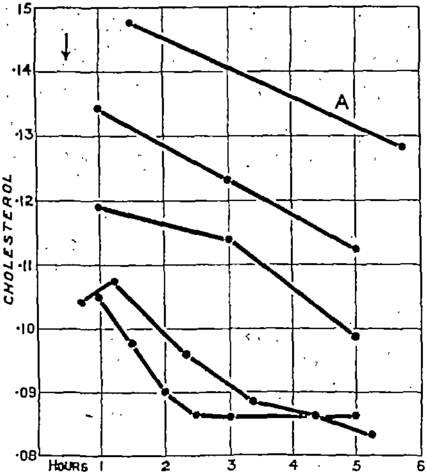
THIS investigation was undertaken to assess the diagnostic value of an estimation of the amount of cholesterol in the blood in cases of supposed cholelithiasis. Before investigating patients known to be suffering from this condition it is obviously essential to decide what can be considered as normal, and to define the limits of the normal, especially as there is considerable variation in the figures given by different authorities both for the mean value and the range of value.

In selecting a method for determining the amount of cholesterol one was chosen in which the quantity of blood withdrawn from the patient was large enough to ensure accuracy, but not so large that one or more withdrawals might impair the general condition, and was, comparatively speaking, easily and quickly carried out. The method was that advocated by Myers in his book,[1] and described originally in papers by Gorham and Myers,[2] and Myers and Wardell.[3] It had the disadvantage of being colorimetric and, therefore, open to an inevitable margin of error.

The estimation is carried out after obtaining the Liebermann-Burchard reaction for cholesterol in the fluid to be estimated. The only absolute method of estimating cholesterol is the gravimetric method of Windaus, after precipitation of the cholesterol in combination with digitonin. It is costly and tedious, and requires larger quantities of blood than are practicable in clinical work. Colorimetric estimation of cholesterol after obtaining the Salkowski reaction has no advantage over the other colorimetric method. For Myers' method 1 c.cm. of blood or serum is required, and a calculation is made to determine the number of grammes of cholesterol per 100 c.cm.

The figures for normal subjects given by various workers using different methods are as follows :—

Autenreith and Funk,[4] in a classical paper upon which much subsequent work has been based, give a normal range in whole blood of 0·140–0·100. They estimate against a fall occurs, whilst Mahler,[21] using Leiboff's[22] modification of Myers' method, found that there was a constant rise with ether anæsthesia of an hour's duration. It must be pointed out, however, that this method consists of one estimation on 0·25 c.cm. of blood, and the increases recorded are small. In Table III. are shown figures for whole blood and plasma in cases subjected to ether anæsthesia for periods varying from 45 to 120 minutes. The changes appear to be definitely in the direction of a fall, in one case well marked.



Blood cholesterol in cats under ether anæsthesia. Anæsthetic started at point indicated by arrow.

This point was further investigated in cats over long periods of ether anæsthesia. The blood cholesterol value in the cat is 0·100–0·150, and appears, in contrast to the human subject, to vary with the size of the animal. The specimens of blood were obtained from the femoral vein. The results are shown in the Figure. Part of this fall in the cat might be explained by dilution of the blood with cholesterol-poor fluid to maintain the blood volume against the repeated withdrawal of relatively large quantities (3–6 c.cm.) of blood, the total blood volume of the cat being about 140 c.cm. That it is not entirely due to this is shown by the experiment marked A, made on two estimations only, one taken one hour, and the second five and a half hours after the commencement of anæsthesia. In no case was a fall produced by anæsthesia sufficient to explain that found after the relief and drainage of a case of obstructive jaundice.

Summary.

1. A modification in the technique for estimating the amount of cholesterol in the blood is described. 2. The normal range of value is shown to be greater than is usually realised. 3. Although the average value is raised in subjects suffering from cholelithiasis, estimation on an individual case is useless as a means of diagnosis. 4. The whole blood cholesterol is very markedly raised in the severer degrees of obstructive jaundice, the rise disappearing when the jaundice is relieved by biliary drainage. 5. Ether anæsthesia tends to produce a fall in the blood cholesterol, but this can be responsible for only a small part of the fall after biliary drainage. 6. The blood cholesterol tends to maintain a constant level in any normal human subject.

This work was carried out during my tenure of a research scholarship at St. Thomas's Medical School, and I am indebted to my colleagues for access to cases under their charge.

THE CAUSATION AND TREATMENT OF DISPLACED MANDIBULAR CARTILAGE.

BY CECIL P. G. WAKELEY, F.R.C.S. ENG., F.R.S. EDIN.,

SURGEON AND LECTURER ON SURGERY, KING'S COLLEGE HOSPITAL.

THE temporo-mandibular joint, although a somewhat complex structure, is nevertheless very stable and dislocation of the joint itself or of its meniscus or fibrocartilage is uncommon.

Displacement of the mandibular cartilage is a rare accident and this is probably due mainly to the shape and attachments of this meniscus. The fibrocartilage is a dome-like structure very closely applied to the convexity of the mandibular condyle. As far as thickness is concerned it is irregular, being very much thicker in its centre and anteriorly (see Fig. 1); between these two thickenings there is a distinct depression. The posterior part of the cartilage is very thin and passes well down over the posterior surface of the condyle and fuses behind with the capsule. I have examined over 50 specimens of the mandibular fibrocartilage in the anatomical department at King's College and in the post-mortem department at King's College Hospital and all conform to the description I have given. This description is, however, at variance with the descriptions given in the current standard text-books of anatomy, the most common description being that the interarticular fibrocartilage is an oval plate thinnest at the centre, where it is occasionally perforated, and thickest posteriorly. I have never seen a perforated interarticular fibrocartilage in this joint in either young or old subjects. The anatomical description to which most of the text-books conform must have been handed down for generations and nobody has troubled to investigate the matter and verify the commonly accepted description. Most text-books of anatomy contain quite good sectional diagrams of this joint which, to the most casual reader, are obviously at variance with the text description.

The temporo-mandibular joint is divided by the fibrocartilaginous disc into two cavities [illegible] provided

An attempt has been made in Tables II. and III. to investigate any relationship which may exist between various types of hæmolytic streptococci and the clinical aspects of the disease in the Ilford series of cases.

TABLE II.—*Incidence of Early Severity of Disease According to Type of Hæmolytic Streptococcus.*

Type ..	I.	II.	III.	IV.	Inagg. hæm. strep.
Pyrexia duration in hours*	41·1	41·5	38·8	20·9	35·2

Abscess	1	—	—	—	—
Vaginitis	—	—	—	1	—
Rheumatism ..	—	—	—	1	2
Albuminuria ..	—	—	—	—	1

This table is exclusive of complications found to be due to a different type of hæmolytic streptococcus to that found in the primary infection.

Tables II. and III. indicate that types 1, 2, and 3 resemble each other in producing the most severe initial symptoms of scarlet fever, type 4 the mildest, while the inagglutinable group occupies an intermediate position. Type 2 appears to be the most likely to produce complications, type 4 the least, type 3 more than type 1. The inagglutinable group varies from frequent to low incidence of complications. These results confirm those of Gunn. When, however, it is remembered that 53·9 per cent. of the hæmolytic streptococci in our series, and 34 per cent. in Gunn's series were not typeable, it is obvious that it is unsound to base any final conclusion on these figures. In addition, it should be noted (1) that the numbers dealt with are small, and (2) that more complications would be present if those due to a different type of organism to that in the primary infection were included. In 24 cases where hæmolytic streptococci were found in the throat on admission, they were found also in the complication. The hæmolytic streptococcus in the primary infection and in the complication were apparently the same in 14 complicated cases, although in six of the cases the streptococcus, either from the fauces on admission or from the complication, was not typeable. The complications which occurred in the 14 cases were: relapse (1); rhinitis (3); abscesses (3); puerperal fever (1); otitis (6); mastoiditis (7). The streptococcus in the primary infection and in the complication was apparently different in ten complicated cases, although it will be noted that in a number of cases the streptococcus in the complication was not typeable.

The results given in Table IV. appear to show that some complications in scarlet fever are due to reinfection with a different type of hæmolytic streptococcus to that in the primary infection. Although cross-infection with septic complications has been known for many years as an administrative problem in isolation hospitals, it is not clear that either our results or those of Gunn definitely demonstrate that such infection is always due to a streptococcus of a different type from that in the primary infection.

The inagglutinable group of hæmolytic streptococci appears to be made up of: (1) strains of hæmolytic streptococci which do not agglutinate with the type sera under any conditions, and (2) hæmolytic streptococci which under certain conditions lose or acquire the power to agglutinate the type sera. For instance, in ten cases in our series it was found that inagglutinable strains of hæmolytic streptococci on repeated subculture yielded an organism agglutinable with one of the four type sera. This fact prevents any dogmatic deductions being drawn from any statistics as to incidence of type, severity of type, or incidence of complications in relation to type. Where complications have been shown to be due to a different type of hæmolytic streptococcus, one must omit all cases belonging to the inagglutinable group, for the strain may have changed in the same patient from a typeable to a non-typeable strain, or vice versa. Although four distinct types can be differentiated by serological means, before these types are accepted as being of clinical value, further investigation is required as to (1) antigenic overlapping, and (2) interconvertability of the four types.

TABLE IV.

Type at onset of attack.	Complication.		Type at onset of attack.	Complication.	
	Nature of.	Type.		Nature of.	Type.
I.	Tonsillitis.	Inag.	III.	Rhinitis.	II.
II.	”	IV.	III. & Inag.	”	Inag.
III.	”	Inag.	IV.	”	II.
I.	Rhinitis	”	IV.	”	Inag.
II.	”	”	II.	Vaginitis.	I. & Inag.

In considering the question of complications being produced by reinfection with a different type of hæmolytic streptococcus, one has to consider also the possibility of the original infection being caused by more than one type of hæmolytic streptococcus, although only one type has been found by the methods used. The same problem exists as in the investigation of the virulence of diphtheria bacilli, where non-virulent and virulent colonies may be present. If the investigator happens only to subculture the one type of colony, an erroneous result is obtained.

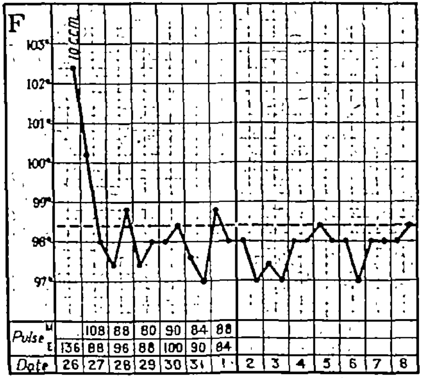
Gunn[6] has stated that in a series of non-serum treated cases, failure to acquire complete immunity was never found in patients infected by hæmolytic streptococci of the types 1, 2, and 3. We found that, including all sizes of reaction, cases which were infected with types 1, 2, or 3 gave the least number of positive Dick results during convalescence, and those with type 4 the greatest number. We analysed the results of the bacteriological examination of 29 cases admitted from 14 families. These showed type 2 in three families, type 4 in one family and inagglutinable streptococci in four families, while in six families, one or more members showed one of the four types, while the other member had an inagglutinable strain.

Gunn and Griffith[7] have stated that, although 55 patients in their series were discharged from hospital "carrying" hæmolytic streptococci, as far as could be ascertained none of these gave rise to any return cases. In the Ilford cases, however, hæmolytic streptococci were found in five patients, examined at various periods from 11 to 21 days after their discharge from hospital, who had given rise to eight return cases in their own families. Of these five patients, three showed inagglutinable streptococci, one showed type 2, and one type 3, while the fifth showed a mixture of inagglutinable streptococci with type 4. We were only able to obtain positive results in three of the return cases. (In one of these, the infecting case had inagglutinable streptococci, while the two return cases both had inagglutinable streptococci. In the other case, while the infecting case had inagglutinable streptococci, the return case showed type 2 hæmolytic streptococci.)

Effects of Serum Treatment.

Since April, 1926, all cases of scarlet fever admitted to the Ilford Isolation Hospital have been treated with scarlatinal antitoxic serum. Every case was given antitoxin as a routine measure because: (1) as scarlet fever antitoxin is a specific remedy it should be of value in every case of disease due to the specific organism, and (2) mild cases of scarlet fever may yet develop severe complications, and it is only by administering the serum to all cases that such complications may be avoided.

The series which we describe comprises 670 consecutive admissions. Only concentrated serum was used, and the routine dose was 10 c.cm., injected intramuscularly. Repeated doses were given in 7 per cent. of cases. Intravenous administration was not used as a routine measure because it was considered unjustifiable to expose young children to a possible fatal therapeutic risk in a disease which at the present time is usually non-fatal. Our policy in this respect is confirmed by Toomey and Dolch,[8] who had three deaths with anaphylactic symptoms out of 40 patients injected intravenously, and also by the series of 404 cases treated intravenously by Banks and Mackenzie,[9] where one death with anaphylactic symptoms resulted. We are of the opinion that intravenous therapy should be reserved for toxic cases. In our cases the intramuscular administration of serum was attended by no ill-effects.



Temperature chart of a female patient aged 27, admitted to hospital with scarlet fever on first day of rash, showing critical fall of temperature after injection of 10·0 c.cm. of antiscarlatinal serum. In this case the infecting organism was a streptococcus of type 2.

A serum rash occurred in 24·5 per cent. of the cases. It caused very little inconvenience, and was usually accompanied by no rise in temperature. No other symptoms of serum sickness were observed. Of 27 cases desensitised owing to a previous history of administration of serum, 14 developed a serum rash with no other symptoms. In all our cases we administered calcium salts, as suggested by Rolleston,[10] and although it is impossible to give any statistical evidence, our opinion is that they reduced the incidence of severe serum sickness. (We observed, for instance, in the diphtheria ward that when the administration of calcium salts was discontinued for a time, serum rashes were much more severe and accompanied by more constitutional disturbance.) The effect on the patient of the administration of the serum was in all cases very marked. The temperature fell to normal by crisis in over 60 per cent.; in some cases it tended to be unsettled after the fall. There was a rapid improvement in the subjective condition and relief of the faucial congestion. There appeared to be no relationship between the day of the disease on which the serum was given and the effect on the pyrexia. Toxæmia is combated by antitoxin whether the serum is given on the first or the fifth day of the disease, but antitoxin will not repair the damage done to the tissues before administration.

It is extremely difficult to produce any satisfactory evidence of the value of scarlatinal antitoxic serum as a routine measure in all cases, as at the present time this disease is so mild. Other writers have attempted to assess it by stating (1) that the length of stay in the hospital can be shortened, (2) that the incidence of complications can be considerably reduced, and (3) that septic complications can be avoided. As the temperature becomes normal 24 to 36 hours after administration of the serum, a large proportion of the cases could be discharged within a fortnight or less, and if this were done (as by Banks and Mackenzie),[9] the number of complications which would occur in hospital would be very considerably reduced. Unless, however, all the cases were systematically followed up for some weeks after their discharge from hospital, no true indication of the number of complications could be obtained. The early discharge of patients suffering from scarlet fever has the advantage of minimising the risks of cross-infection, and all complications arising from this cause. In our own series, mild uncomplicated cases were usually discharged after 28 days, while complicated cases averaged a stay in hospital of seven to eight weeks. It is impossible to quote any figures which would be of use in illustrating the value of scarlatinal antitoxic serum in reducing the length of stay in hospital, as many mild non-serum treated cases of scarlet fever which are uncomplicated could be discharged after 28 days or even before. We can only give the opinion that with the routine use of antiscarlatinal serum the number of such patients is considerably increased.

In assessing the incidence of complications, the selection of "control" cases is most important, and constitutes a very difficult and almost an insoluble problem. Alternate cases used as controls are open to the objection that the control may be milder or more severe than the treated case. A chosen series of cases for many years is also of no value, as the type may be milder and the complications different in different years. A good example of the variation of one complication in different epidemics is given by the late C. B. Ker.[11] In 15,210 cases comprising three series, the percentage incidence of nephritis was 11·0, 5·04, and 8·75 respectively. Tables IVA. and V. show the variation in the incidence of complications in our own cases, (*a*) taking the first 500 and comparing them with the following 170, and (*b*) comparing the first 18 months with the second 13 months.

TABLE IVA.—*Serum-treated Cases.*

First 500 cases	(per cent.)	Following 170 cases (per cent.)
Adenitis ..	.. 13·2	10·0
Otitis ..	.. 5·6	7·0
Nephritis	.. 1·5	0·58
Relapse ..	.. 4·8	—

TABLE V.—*Serum-treated Cases.*

April to Sept., 1927. 18 months.		Sept., 1927, to Oct., 1928. 13 months.
No. of cases	301.	No. of cases 369.
	per cent.	per cent.
Adenitis	7·6	10·2
Otitis	4·0	7·6
Mastoiditis..	0	1·3
Albuminuria (including nephritis)	3·3	3·3
Nephritis	2·3	2·15
Rheumatism	1·6	1·9
Relapse	4·3	2·7
Total ..	23·1	35·15

In a review of the literature on this subject, J. A. Toomey[12] very rightly attacks the whole question of inadequate control, and emphasises the importance of the great factor of variability in scarlet fever. It is not possible to include all the incidental, accidental, and variable factors necessary to select true "control" cases in scarlet fever. Such an accidental factor as crowding of wards in epidemics, leading to an increase in the number of complications, does not appear in published statistics relating to complications. At the Ilford Isolation Hospital during the period under review, 33 per cent. of the cases developed complications, as shown in Table VI.

TABLE VI.—*Complications in 670 Serum-treated Cases of Scarlet Fever.*

Nature of complications.	Cases and per cent.	Nature of complications.	Cases and per cent.
Adenitis	83 (12·4)	Suppurative adenitis	5 (0·7)
Albuminuria: Total (including nephritis)	22 (3·29)	Mastoiditis	5 (0·7)
Nephritis	15 (2·2)	Pneumonia and broncho-pneumonia	2 (0·3)
Otitis..	40 (6·0)	Pharyngeal abscess..	1 (0·15)
Rheumatism ..	12 (1·8)	Bronchitis	2 (0·3)
Relapse	23 (3·2)	Pyelitis	1 (0·15)
Rhinitis	58 (8·7)	Abscesses	2 (0·3)
Tonsillitis— Total	19 (2·8)	Peritonitis (and puerperal sepsis) ..	1 (0·15)
Suppurative ..	6 (0·9)	Vaginitis	3 (0·45)
Paronychia	28 (4·2)		

Mortality = 0·45 per cent. (exclusive of 1 case of puerperal fever).

Day of disease = day of rash.

Table exclusive of rhinitis, adenitis, and albuminuria at onset, and of complications following relapse.

Only one toxic case was treated and, although improvement was manifested for a time after large doses of scarlet fever antitoxin (180 c.cm. being given within three days) the patient succumbed from lobar pneumonia. A second death occurred in a woman admitted suffering from scarlet fever and puerperal fever. Inagglutinable hæmolytic streptococci were present in the throat and uterine cervix. The patient died after an operation for peritonitis.

Friedemann and Deicher[13] found hæmolytic streptococci in the pus of septic complications but not in the desquamation nor in the urine. Our own results confirm this, as hæmolytic streptococci were found in the nose, throat, and in the pus of septic complications, but not in the urine in cases of nephritis. It will be noted that, although antitoxic serum was administered on admission, yet suppurative complications occurred. These included 40 cases of otitis media, 6 of suppurative tonsillitis, 4 of suppurative adenitis, 1 of suppurative adenitis followed by pharyngeal abscess, 2 of other abscesses, 3 of vaginitis, 28 of onychia, and 5 of mastoiditis. The cases of mastoiditis we have grouped in Table VII., and have included 4 cases of mastoiditis which occurred in 1929.

TABLE VII.

Day of adminis. of antitoxin.	Dose of antitoxin.	Day of onset of otitis.	Dick test.	Day of onset of mastoiditis.	Type of hæm. strep.		
					Fauces on admission.	Pus from ear.	Pus from mastoid.
2	10	7	Neg.	14	Inag.	Neg.	Neg.
16	15	16	Pos.	30	III.	III.	III.
2	20	6	,,	35	Inag.	Inag.	Neg.
1	10	39	,,	54	,,	,,	Inag.
2	10	1	Neg.	51	Neg.	Neg.	Neg.
2 to 5	60	4	,,	5	III.	Staph.	III.
2 to 3	30	4	,,	5	II.	II.	II.
1	10	32	,,	35	I.	I.	I.
2	10	14	,,	42	III., I., & II.	Neg.	Inag.

It will be observed from this table: (1) that the early administration of serum did not prevent the development of otitis media nor of mastoiditis; (2) that repeated doses of serum did not prevent the early onset of mastoiditis; (3) that the Dick test was negative six times out of nine when mastoiditis developed; (it was also negative six times out of seven at the onset of otitis media); (4) that the type of hæmolytic streptococcus when found was the same in the throat, ear, and mastoid. Apparently, therefore, routine treatment of cases of scarlet fever with antitoxin will not prevent suppurative complications. It is probable that in such cases the streptococcus has invaded the tissue and the antibacterial action of the serum is not sufficient to combat it. Ten of the 15 cases of nephritis occurred within the usual period, the second to the fourth week, while five were met with later. Thus the appearance of this complication is not delayed by treatment with antitoxin. Two cases of nephritis following relapses are not included in the total. Nephritis was rarely accompanied by pyrexia unless another complication was present at the same time—for example, adenitis. Œdema was limited to the eyelids. Neither diet, period of rest in bed, nor initial severity of the disease could be designated as causes of the nephritis. Incidentally, there appears to be no reason why scarlet fever patients should not receive adequate diet and get up as soon as their local and general conditions permit. It is doubtful whether repeated doses of serum would prevent nephritis. All we can say is that only one case out of over 200 has developed this complication since repeated doses of serum were used more widely. The Dick test was usually negative at the time of the clinical manifestation of the kidney condition, showing that uncombated toxæmia was not occurring in the body at that time. The following questions arise: when and how are the kidneys damaged? why are some cases singled out? and why does the incidence of nephritis vary so much in different years? It seems that in some individuals either (1) the glomeruli of the kidneys are very susceptible to damage by scarlet fever toxin, or (2) they are unable to secrete toxin at the ordinary rate, or (3) their kidney cells are unable to recover from toxic action, or (4) there is another factor present in addition to the initial toxæmia—e.g., acidosis. This is believed to be the cause of the condition by Berry[15] and Carter.[16] An acute recrudescence of nephritis in hospital appears to be rare.

Case No. 55/28, aged 6¼ years, was admitted on the first day of a typical scarlet fever ordinary attack. 10 c.cm. of antitoxin were given and type 3 *S. scarlatinæ* found in faucial swab. On the 8th day he developed cervical adenitis, on the 13th day tonsillitis, and on the 14th day nephritis, which cleared up after 12 days. On the 60th day the patient was up in ward; on the 70th day he had rhinitis with a *S. scarlatinæ*, type 2. On the 83rd day he developed nephritis, but with no streptococci in the urine. He recovered.

Immunity in Convalescence.

We have previously expressed our view on the effect of scarlatinal serum in increasing the number of Dick-positive reactors during convalescence in scarlet fever.[17] This has since been confirmed by Brown.[18] We also considered this question in relation to the incidence of relapses. Table IV. shows that, whereas in the first 500 cases in which no special precautions were taken the relapse rate was 4·6 per cent., no relapse occurred in the last 170 cases when the precautions mentioned in our previous article were taken. As in the cases described by Griffith and Gunn,[7] the relapses occurred in Dick-positive cases. Unfortunately in only one of the relapses were we able to obtain hæmolytic streptococci in the fauces, both in the primary infection and in the relapse, and in this case the organism, in both instances, was inagglutinable.

D. S. Sutherland[19] has reported on the value of the active immunisation with scarlet fever toxin of Dick-positive reactors convalescent from scarlet fever. This method was tried by us in 56 cases which gave a Dick-positive result at the end of the third week of disease. Of these cases one showed hæmolytic streptococci on admission to hospital and three had mixed types of streptococci; of the remaining 53, 26 (49 per cent.)

were converted from Dick-positive to Dick-negative reactors before their discharge. The average dosage of scarlet fever prophylactic employed was 500, 1000, 2000, 2500, 3750, and 5000 units at weekly intervals. Some of the cases remained in hospital only two weeks from the time of the first dose. These might have been converted if they had had the full course. Nineteen cases were converted to negative after one dose in seven days; one case after two doses in 14 days; three cases after fourteen doses in 21 days, and of the remaining three cases, one was converted after nine doses in 70 days. (This was a case of mastoiditis which had been operated upon.) The Dick-positive reaction became fainter with succeeding doses of the prophylactic. The classification of the cases according to the type of organism concerned is given in the following table.

Type.	I.	II.	III.	IV.	Inag.	Total.
Converted.. ..	3	4	1	1	17	26
Not converted ..	2	2	1	3	19	27

Little can be deduced from this table owing to the small figures, but the cases infected with type 4 appear to be less readily rendered immune than those infected by other types. Twenty-one of the cases had or developed complications; 47·9 per cent. of these were converted. Two of type 4 complicated cases were not converted. We have formed the opinion that, although it is possible to convert convalescent patients who are Dick-positive reactors to Dick-negative reactors by a course of injections of scarlatinal toxin, yet the proportion of cases so converted within a short period of time is insufficient to be of administrative value—that is, it is not of value for the prevention of reinfection during the further stay in hospital. We consider that the more practical method is either to isolate such cases or to immunise them passively after desensitisation with antiscarlatinal serum.

The Effect of Serum Treatment on Complications.

Although we do not suggest that it is in any way an adequate control, we have compared in Table VIII. the percentage of complications in 517 consecutive cases admitted during 1922–25 with our present series.

TABLE VIII.—*Ilford Isolation Hospital.*

—	April, 1926–October, 1928.	1922–1925.
	Serum-treated 670 cases (per cent.)	Non-serum treated 517 cases (per cent.)
Adenitis	12·4	21·8
Albuminuria ..	3·20	8·7
Otitis	6·0	9·7
Rheumatism ..	1·8	5·8
Total percentage..	23·40	46·0

The control is of some value in that our present series consists of cases occurring during an epidemic period when scarlet fever was of a severer type than in the preceding three years. It will be noticed that the reduction in the incidence of complications is most marked in rheumatism, a toxic condition, and least marked in otitis, a septic condition. After a careful scrutiny of the 223 complicated cases we have not been able to establish the thesis that the day of disease on which serum is given influences the incidence and day of onset of complications in scarlet fever. This work does not support the view advanced by McLachlan and Hunter,[10] Scott,[11] and Craig,[12] that the earlier the serum is given the less the incidence of complications. In our opinion there are other factors determining whether a case will be a complicated one or not. Possibly it is not a question of "days" after the appearance of the rash, but the period prior to the exanthem or at its actual onset when the streptococcus is enabled to penetrate before antibacterial resistance is developed. Table IX. is an analysis of the complications with the day on which the serum was given and the number of times the complication occurred.

TABLE IX.

Day serum given.	Suppurative adenitis.	Rhinitis.	Otitis.	Nephritis.		Rheumatism.		Relapse.	Tonsillitis.	Supp. tons.	Onychia.	Mastoiditis.	Pneumonia.	Pharyngeal abscess.
				2–4 weeks.	Later.	Early.	Late.							
1st	3	10	12	3	—	2	3	3	3	—	8	1	1	1
2nd	—	21	13	—	1	2	—	13	6	1	10	3	1	—
3rd	1	9	7	4	—	—	1	4	3	3	6	—	—	—
4th	1	5	2	1	1	2	2	3	1	1	1	—	—	—
5th and over.	—	4	6	2	3	—	—	—	2	1	3	1	—	—

A suggestion has been made that complications in cases of scarlet fever are delayed and not prevented by the use of scarlatinal antitoxin.[14] The administrative procedure as regards routine day of discharge from hospital will influence the number of delayed complications. In some hospitals all clean cases are discharged at the end of four weeks or before; in others not until the sixth week. Therefore any complication arising in hospital in a previously uncomplicated case after the twenty-eighth day might be classified as a delayed complication. McLachlan and Hunter[10] in serum-treated cases have recorded 3·75 per cent. with complications (excluding debility) occurring primarily after discharge from hospital; in addition, 6·6 per cent. recurring after discharge from hospital, a total of 10·35 per cent.

In a series of 500 non-serum treated cases followed up at Bristol, 12 per cent. of cases suffered from complications after discharge from hospital.[14] The fallacy in collections of figures of this kind is that—apart from cases actually seen by a medical practitioner after discharge—the report is based on the history given by patients or parents. Even so, our series of serum-treated cases does not compare unfavourably with non-serum treated ones. 557 of the serum-treated cases discharged from the Ilford Isolation Hospital were investigated (313 by medical officers and 244 by sanitary inspectors). 10 per cent. of the cases developed complications after discharge, of which 2 per cent. were recurrences of conditions arising in hospital.

Number of Times Complications Occurred.

Rhinitis	21	Pleurisy	1
Otitis	11	Heart	3
Rheumatism	7	Chorea	1
Nephritis	4	Onychia	2
Adenitis	2		

After relapses in hospital two cases had recurrence of rhinitis; one developed a primary otitis and one a primary otitis and nephritis, one endocarditis, and one rheumatic fever after discharge. The figures exclude anæmia and debility.

Results and Conclusions.

1. Out of 265 cases, 191 or 70 per cent., on admission showed hæmolytic streptococci in their fauces.

2. Of the hæmolytic streptococci in the above series, 46·1 per cent. of the cases could be classified under one of Griffiths' groups, the remaining 53·9 per cent. being inagglutinable with the type sera. Certain of these strains became agglutinable on repeated subculture.

3. In view of the large percentage of inagglutinable hæmolytic streptococci, it is impossible accurately to correlate the type of streptococcus with the clinical type of scarlet fever. As far as our present knowledge

goes, however, type 4 appears to be the least virulent, and type 2 the most virulent of the typeable streptococci.

4. In 24 complications a hæmolytic streptococcus was found both in the fauces and at the site of the complication; in ten cases the type was different in the latter to the former. This appears to indicate cross-infection with a different type of streptococcus. In view of the presence of inagglutinable strains of streptococci and the possibility of an original mixed infection, no dogmatic statement can be made at present.

5. The results of routine treatment of cases of scarlet fever with antiscarlatinal serum are good, but do not compare with the use of antidiphtheritic serum in diphtheria. Our experience does not bear out the statement of Toomey and Dolch[8] that serum sickness is usually more severe than the disease itself. Such evidence as we have at our disposal indicates that antiscarlatinal serum markedly reduced the number of toxic complications. It also reduces the number of septic complications, but not so markedly. It does not delay the onset of complications.

6. Modern investigations show (*a*) that there is a considerable proportion of Dick-positive reactors in convalescent scarlet fever patients, (*b*) that the number is increased in cases treated with antiscarlatinal serum, (*c*) that there is a certain amount of evidence that cross-infection with different types of hæmolytic streptococci occurs, (*d*) that hæmolytic streptococci persist longer in the throats of patients nursed in hospital than they do in cases nursed at home.[23] We are of the opinion that the present system of nursing scarlet fever patients in general wards will ultimately have to be discontinued, and, if such patients have to be removed to hospital, they will require to be treated in cubicle wards at least until their immunity and—when our knowledge is a little more advanced—their type of infection can be accurately determined.

7. The active immunisation of convalescent scarlet fever patients who are Dick-positive with scarlatinal toxin is not a satisfactory solution of the administrative problem of dealing with such cases.

QUEEN'S HOSPITAL FOR CHILDREN.—This hospital of 134 beds last year received 1818 in-patients. Their average stay was 24 days and their cost £11 1*s.*; the 32,708 new out-patients cost 5*s.* 8*d.* each. The Bexhill Home received 183 in-patients at a cost of £18 14*s.* 10*d.* each. The hospital has an arrangement with the London County Council for the dental treatment of school-children, and is one of the largest centres in London for such cases. Towards the income of £33,514 patients contributed £5927, but there was a deficit of £722.

Clinical and Laboratory Notes.

DIAGNOSIS AND TREATMENT OF ANÆMIA IN SCHOOL-CHILDREN.

WITH SPECIAL REFERENCE TO THE HÆMOGLOBIN CONTENT OF THE BLOOD.

BY NANCY K. GIBBS, M.R.C.S. ENG., D.P.H.,
ASSISTANT MEDICAL OFFICER OF HEALTH, CARDIFF.

THIS investigation was begun in January, 1928. At first nothing more was done than to record on the medical card of each child the hæmoglobin content of the blood on admission and on discharge from the open-air school. The great majority of children admitted to this open-air school belong to that group of subnormal physical health usually labelled "malnutrition and anæmia," or "pretuberculous," and there are thus few definite physical signs other than pallor, perhaps palpable cervical glands, and anatomical unfitness in weight or build, together with a history either of recurrent illness, often vague in character, or of living or having lived in association with a relative suffering from tuberculosis. Often a combination of these facts is reported.

To estimate the hæmoglobin von Fleischl's hæmometer was used. In order to compare the figures with those of other investigators the apparatus was tested against Haldane's hæmoglobinometer, which appears to be the most commonly employed, but which could not be used in this experiment as there is no coal-gas at the school. Ten persons were tested by both methods and, excluding three cases where there was recognisable technical error—viz., in completely filling the Haldane capillary tube—the results were: four cases gave identical readings; two cases gave readings 2½ per cent. higher with von Fleischl's apparatus; and one case gave a reading 1¼ per cent. higher with von Fleischl's apparatus.

If a reading on von Fleischl's apparatus were (e.g.) above 50 but below 55 it was called 52½. Thus the results indicate that the two methods give closely related values. A dark room and an electric lamp of the same power were always used with von Fleischl's apparatus.

The Normal Hæmoglobin Percentage.

Some difficulty is felt in deciding what the normal percentage of hæmoglobin is in a "healthy" child. S. C. Dyke[1] has stated that "whatever method of estimating hæmoglobin is used the percentage in normal people (evidently adults) is below 100." He goes on to say that 80 to 105 may be regarded as being within normal limits, 60 to 80 as showing anæmia, and that figures below 60 indicate need for treatment.

In the course of the present inquiry the hæmoglobin was estimated in 45 children who were said to be "well"—i.e., they were not receiving medical attention and were attending regularly an elementary school in the centre of the town. Table I. gives the figures in this control group and in the first group of 55 children examined at the open-air school. The latter when tested had already been in the open-air

TABLE I.

Hæmoglobin (per cent.).	Control group (No.).	45 children (per cent.).	Open-air school group (No.).	55 children (per cent.).
Below 40	0	—	0	—
40– 50	1	2·2	1	1·8
51– 60	3	6·6	10	18·0
61– 70	11	24·4	23	41·8
71– 80	12	26·6	11	20·0
81– 90	13	28·8	8	14·5
91–100	3	6·6	0	—
101–105	2	4·4	0	—
106–110	0	—	1	1·8
111–115	0	—	1	1·8
116–120	0	—	0	—
Total	45	99·6	55	99·7

---

[1] Dyke, S. C.: THE LANCET, 1928, ii., 936.

school for about three months. Both groups are composed of approximately equal numbers of boys and girls, and the ages are similar.

This table shows that in the control group the majority (36 children) give hæmoglobin estimations between 61 per cent. and 90 per cent., while in the open-air school group the majority of the children (44) give estimations between 51 per cent. and 80 per cent. —i.e., the subnormal group of children have hæmoglobin values about 10 per cent. lower than those of the healthy children. Again it is evident that whereas in the control group 32·2 per cent. of the children give readings of 70 per cent. or lower and 66·4 per cent. higher readings, almost exactly the reverse is true for the open-air school-children, since 61·6 per cent. of these children give readings of 70 per cent. or lower and 38·1 per cent. only give higher readings. This suggests that the line of demarcation between health and ill-health might be placed at about 70 per cent.

Results of Attendance at Open-air School.

By Easter, 1929—at the end of four terms during which this work has been carried out—it was observed that between 50 and 60 per cent. of all the children admitted to the open-air school gave a higher hæmoglobin value, whatever their original figure, when tested before discharge from the school. Table II. gives the details for the first 55 children who were discharged; they are the same children as in the first table.

TABLE II.

Hæmoglobin estimation.	No. of children.	Per cent.
Increased	31	56·3
Unchanged	6	10·9
Decreased	18	32·7
Total	55	99·9

This percentage of improvement remained fairly constant for the children who were discharged each term, although the time spent in the school varied in individual cases by as much as one year. It is a day open-air school where the children remain from 9 A.M. until 4.30 P.M. in winter and 5.30 P.M. in summer; dinner and tea are provided, also milk at 10.15 A.M. It should be noted that all the children improve in physical fitness as judged by improved general appearance and increased muscle tone, appetite, weight, and activity.

Result of Administering Iron.

As the result of dissatisfaction with the relatively low improvement rate in the children's hæmoglobin values, it was decided to administer iron, following the lines of the work done by Dr. Helen Mackay,[1] adopting provisionally as normal the figures 80 per cent. to 105 per cent. The children to whom iron was to be given were selected as follows: Eighteen children were picked out by the school nurse as not having improved in general condition, in her opinion, in spite of fairly regular attendance for between 6 and 12 months. All but 4 of these gave hæmoglobin figures under 80 per cent., but 11 (61 per cent.) gave a higher reading than on admission, thus falling in with the improvement percentage found each term in the children discharged. The 14 children with hæmoglobin values below 80 per cent. were given iron, and are known as the "special" treated group. Of 82 other children in the school at that time, 51 had hæmoglobin values under 80 per cent.; the first 25 in alphabetical order of this 51 were given iron and the remaining 26 were not given iron, in order to form a control group. In all, 39 children received iron.

The mixture given was iron and ammonium citrate in chloroform water. The selected children were given two doses daily after meals, those over 10 years of age receiving a total of grs. 15 daily and those under 10 a total of grs. 7½ daily. This medicine was given five days weekly for ten weeks. There were a few complaints of constipation but none of indigestion. Clinically there was no striking improvement in the colour of skin or mucous membrane.

The results, which are surprising in view of Dr. Mackay's work, are given in Table III. Only 33 of the original 39 who were given iron were available for the final estimation, and the control group also became smaller in number owing, in both groups, to absence from school during the period of experiment.

TABLE III.

Hæmoglobin estimation.	"Special" treated group.		Unselected treated group.		Control group.	
	No.	Per cent.	No.	Per cent.	No.	Per cent.
Increased	1	8·3	6	28·5	5	29·4
Unchanged	4	33·3	3	14·3	4	23·5
Decreased	7	58·3	12	57·1	8	47·1
Total	12	99·9	21	99·9	17	100·0

The numbers are small but clearly indicate that iron administered as described has had no significant effect on the hæmoglobin content of the blood in subnormal children, most of whom are pallid and debilitated, are described by clinical observers as "anæmic," and give a confirmatory reading on von Fleischl's hæmometer. This result contrasts strikingly with the observation that between 50 and 60 per cent. of the children admitted to the open-air school give a higher hæmoglobin estimation on discharge than on admission without being given an iron tonic.

Summary.

1. Hæmoglobin estimations were made in children on admission and on discharge from an open-air school.
2. The apparatus used to estimate the hæmoglobin was von Fleischl's hæmometer, which was compared with Haldane's hæmoglobinometer, and the difference in the figures given by the two instruments was found to be small.
3. A number of healthy children were tested to try to find the "normal" hæmoglobin value in children.
4. It was observed that between 50 and 60 per cent. of the children gave higher hæmoglobin readings on discharge than on admission to the open-air school.
5. Iron was administered in an attempt to obtain a higher number of increased hæmoglobin estimations. The effect was negligible.

These observations were made and published with the approval of Dr. R. M. F. Picken, medical officer of health.

THE ACTION OF EPHEDRINE IN RELIEVING CERTAIN PAINFUL ACCOMPANIMENTS OF LEPROSY AND LEPRA REACTION.

BY ROBT. G. COCHRANE, M.D. GLASG.,
M.R.C.P. LOND.,
SECRETARY, BRITISH EMPIRE LEPROSY RELIEF ASSOCIATION: HONORARY MEDICAL ADVISER TO THE MISSION TO LEPERS.

THE treatment of leprosy does not end with the administration of some product of hydnocarpus oil, but must take within its scope the treatment of numerous complicating factors. These complications are frequently more trying than the disease itself. It is here that ephedrine has been found useful.

The first use of ephedrine with which I wish to deal is its employment for the relief of the painful complications of lepra reaction. These are mainly, 1. Nerve pain. 2. Painful swellings of soft tissues. 3. Joint pains and headache. In previous communications to medical journals,[1,2,3] the power of ephedrine to relieve such distressing symptoms has already been demonstrated. The following illustrations afford further confirmatory evidence.

CASE 1.—An Indian male, aged 20. Advanced skin leprosy (B_2–B_3 Muir's classification). Complained of headache and pain all over the body; this was associated with fever ranging from 101°–103° F., and also with the eruption of fresh nodules on both arms. Ephedrine gr. ½ by mouth was given. Within 15 minutes pain and headache were relieved. As fever had persisted for three days 0·02 g. potassium antimony tartrate was given every other day for one week, and the temperature gradually came down to normal.

---

[1] Mackay, H. M. M.: Arch. Dis. Child., 1928, iii., 117.

CASE 2.—An Indian male, aged 35. (Mixed case, $B_2.A_2$.) Complained of much fever, nerve and joint pain; gr. ¼ ephedrine in 1 drachm of water was administered. Within 15 minutes patient said the pain "had been miraculously relieved." Again pot. antim. tart. 0·02 g. was administered, and on second injection temperature returned to normal. On previous occasions patient stated he "had to suffer six weeks of fever."

CASE 3.—A male, aged 14. (B_3.) Complained of local swelling and pain on right side of face associated with fever coming on 12 hours after injection of 4 c.cm. Alepol. Ephedrine gr. ¼ in 4 c.cm. of saline was injected subcutaneously. Pain disappeared almost at once and swelling subsided within 24 hours.

These cases once again illustrate that this drug has a powerful effect in alleviating some of the complications of lepra reaction. Chronic leprosy, however, brings certain painful sequelæ in its train. Therefore it was considered worth while to give ephedrine a trial. The conditions in which the drug was tried were: 1. Nerve pain of a persistent character unaccompanied by fever. 2. Burning and gnawing pains in joints of bones. The former type of pain is probably due to pressure of the contracting fibrous tissue in the nerve sheath, and therefore any relief can only be expected to be transient. The severe bone pains which occur are probably of a trophic nature. The following illustrate the result of ephedrine in such cases:—

CASE 4.—A Hindu female. (Mixed $A_1.B_1$.) Complained of constant gnawing pain in the internal cutaneous nerve of the forearm. The nerve was felt as a thick fibrous cord for about 4 inches, below the elbow. Ephedrine hydrochloride had been given orally with no relief. Half a grain of the drug in 4 c.cm. of saline was then injected underneath and along the course of the nerve. Pain diminished within half an hour, and the patient was comfortable for the next three days. About a week later pain recurred and the injection was repeated, again giving temporary relief. As the pain continued to recur, and because the nerve was so thick, an operation was considered necessary. Under a local anæsthetic about 4 inches of the medial cutaneous nerve of the forearm was exposed and freed from its sheath. The wound was then closed without drainage. The wound healed by first intention and gave permanent relief from pain up to the time of writing.

CASE 5.—A female. Advanced skin type, aged 30. (B_2.) Complained of gnawing pains along the course of the peroneal nerve, until the patient stated that she was unable to sleep. On March 3rd, 1929, gr. ½ was given orally with no relief. On March 5th gr. ½ ephedrine in 4 c.cm. saline was given subcutaneously along the course of the peroneal nerve. Pain diminished to a great extent in 20 minutes, and did not recur until March 26th. On this occasion the injection was repeated and again gave some relief. An operation would in all probability give permanent relief if patient would consent.

CASE 6.—Hindu male, aged 35. Advanced mixed case. ($B_2.A_2$.) Complained of very severe burning pains in hands and feet. Ephedrine gr. ¼ orally gave no relief. Half a grain in 4 c.cm. saline subcutaneously gave relief within half an hour and pain did not recur for several days. On a repetition of the injection pain was again relieved.

CASE 7.—Hindu male, aged 45. Advanced nerve case (A_1–A_2.) Complained of aching in bones of dorsum of foot and hand; bones were markedly tender to pressure. As the patient was strong and healthy it was decided to inject ephedrine intravenously. Because all veins except those in the dorsum of the foot had become blocked the drug was injected into this situation. Relief was marked within 15 minutes, and the tenderness and pressure disappeared. The heart's action was markedly increased in force, but not so greatly in frequency, and a systolic bruit appeared which disappeared in half an hour when the action of the drug passed away.

Conclusions.

From this short series of cases it can be concluded that ephedrine by mouth gives almost instantaneous relief in nerve pains, &c., that accompany leper fever. I could not confirm Green's[2] conclusion that it influenced the pyrexia. For apart from pot. antim. tart. I noticed no effect, and concluded that it was this drug that controlled the fever.

In pains which accompany chronic leprosy ephedrine given subcutaneously, or, if the patient is strong and healthy, intravenously, is worth a trial. For nerve pain of the type described, operation must be eventually resorted to. For bone and joint pain which is so distressing then ephedrine appears to give temporary relief, and therefore is worthy of a trial.

I have to thank Prof. B. E. Read, of Peking, for further supplies of ephedrine hydrochloride, without which this investigation could not have been undertaken.

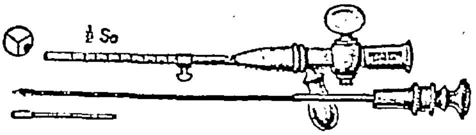
New Inventions.

A PNEUMOTHORAX INDUCTION TROCAR AND CANNULA.

IN the induction of pneumothorax with the Riviere trocar and cannula it is necessary to push the instrument down as far as the parietal pleura, withdraw the trocar, and then push the blunt cannula through the membrane into the potential pleural space. This method is advocated in order to avoid damage to the underlying lung. In practice we have found that it is unsatisfactory because considerable pressure is required to push the cannula through the membrane; the parietal pleura tends to be stripped off the ribs and there is a possibility of damage to the pleura and subsequent pleural shock. Further, if the pleura is not sufficiently anæsthetised the procedure causes a considerable degree of pain. We have found that the best way to use the Riviere induction needle is to penetrate the parietal pleura with the sharp trocar which is then withdrawn. If the end of the cannula is in the pleural space, the manometer shows wide negative respiratory fluctuations. If not, the trocar has to be reinserted and further search for the pleural space ensues. The disadvantages of this method are: (1) if the end of the trocar projects much beyond the end of the cannula there is a possibility of piercing the lung; and (2) it is necessary to withdraw the trocar in order to see the manometric fluctuations. In order to overcome these difficulties, we have modified the Riviere induction trocar, as will be seen from the figure: (a) The point of the trocar is made to project as little as possible beyond the end of the cannula. (b) The trocar is grooved from its point to where the shaft is seen to be narrowed. The narrowing of the shaft is continued as far as where it corresponds to the cannula's side projection to which is attached the rubber tubing going to the manometer and the air reservoir. (c) The cannula does not have the lateral aperture which is a feature of the Riviere needle. The result of these modifications is that there is a continuous air space from the point of the needle to the manometer. Manometric fluctuations are set up as soon as the point of the needle enters the pleural space. The very short point of the needle practically precludes the possibility of damage to the lung. If necessary, air can be injected without withdrawing the trocar. The abolition of the lateral aperture does away with the possibility of air being injected at the same time into the tissues of the chest wall.



The instrument has been made for us by Messrs. Down Brothers, St. Thomas's-street, London.

ANNUAL MEETING IN MANCHESTER.

(Continued from p. 501.)

SECTION OF NEUROLOGY.

THE EPILEPSIES.

Dr. JUDSON BURY (Manchester) presiding, Dr. S. A. KINNIER WILSON (London) opened the discussion with a paper entitled Some Aspects of the Problem of the Epilepsies. He said he was under no delusion as to the complexity and intricacy of the subject. Were epilepsy not so involved a problem it would long ago have received at least a working interpretation, but the truth was that the condition defeated us on many grounds; its ætiology was heterogeneous, its semiology was indeterminate, its pathology dubious, and its therapeutics empirical. For the purposes of the discussion he could only single out one or two aspects to which attention might be usefully directed. They had been chosen intentionally as best calculated to indicate the range of the problem connected with the epilepsies.

1. *Clinical Features of Epileptic States.*

The first difficulty arose from the clinical polymorphism of epileptic phenomena. A major epileptic fit, when seen, was readily diagnosed, but the epileptic state was by no means confined to major seizures. Motor, sensory, psychical, and visceral variants all existed. We had also to consider the pre-seizure and post-seizure disorders. In taking a wide and psychogenic view of the question, the *following points were to be remembered: (1) The* epileptic aura was a sensation and thus a symptom belonging to the psychical series; it was something in consciousness. Herpl had long ago emphasised the hallucinatory nature of the phenomenon. (2) Interruption of the stream of consciousness might or might not accompany epileptic manifestations. Absolute unconsciousness might supervene without aura, but many fits ran their course with conservation of consciousness. (3) The motor condition of the fit usually consisted of convulsive movements. On the other hand, the whole of the motor phenomena might consist in mere flickers of a finger and thumb, quivering facial contractions, or a momentary spasm—even the absence of movement. (4) The sensory elements of a seizure, apart from the aura symptoms, constituted the whole attack. In many instances the aura was not followed by an attack. (5) The visceral components included circulatory, respiratory, vasomotor, rectal, renal, vagal, pupillary, and other phenomena. (6) Post-seizure manifestations embraced varied sets of opposites, from sleep to fugues, stupor to combativeness, speedy recovery to prolonged fatigue. All these phenomena emphasised the heterogeneous nature of epileptic manifestations.

2. *Inheritance of Epilepsy.*

Twenty-one years of practice and hospital experience had convinced Dr. Wilson that the hereditary factor was persistently overrated and the personal, or constitutional factor, underrated. The number of cases in which no hereditary element could be traced far exceeded that in which such a factor seemed responsible. Statistics were quoted by Dr. Wilson to support this contention. He considered that it was impossible to draw any other conclusion than that direct heredity was of little moment in comparison with other inducing factors.

3. *Experimental Production of Convulsions.*

On the experimental side, normal animals could be made to develop convulsions with ease and certainty. Whatever the provenance of laboratory animals, they were also potentially capable of developing epilepsy. Study of methods revealed two main technical procedures for the production of convulsive states. These might be classed as (1) humoral, and (2) neural. These might act separately or interrelatedly.

(1) The *humoral* factor might be defined comprehensively as that component in the production of experimental epilepsy which consists in alteration of the body fluids and biochemical constituents, either mechanically or in connexion with exogenous or endogenous noxæ. Certain general conclusions recently arrived at by Lennox and Cobb showed that: (1) acidosis tended to inhibit, and alkalosis to augment seizures; (2) an increased tension of oxygen in the tissues tended to inhibit and a decreased tension to augment seizures; (3) œdema of the brain tended to increase, and dehydration to diminish seizures. Although these generalities merited attention the modes of action of the various factors had not been satisfactorily determined, and the separateness of their functions was not established. In other words, we were not in a position to say that the mechanical and the toxic components were always in essence contrasted or in their effect mutually and invariably independent.

As for the *neural* mechanism, it had been known for years that direct excitation of neural centres could result in the development of unilateral or generalised epileptic attacks.

4. *Occurrence of Convulsions in Pathological States.*

If the deductions of the experimentalist in respect of epileptic determinants were to prove of value they must be capable of substantiation from the clinical side—that is to say, there must be evidence that these, or some or other of these, played a part in the production of epileptic syndromes under pathological circumstances. Taking neural conditions first, we recognised a large number of diverse organic cerebral states in which epilepsy in one or other form made its appearance: (1) Cerebral tumours; (2) cerebral infections and toxic infections—e.g., encephalitis, syphilis; (3) cerebral toxic degenerations or scleroses (disseminated sclerosis, &c.); (4) cerebral trauma; (5) certain varieties of congenital and heredo-familial disease.

Humoral and vascular cerebral pathological conditions were: (1) disease of blood-vessels (thrombosis, arterio-sclerosis, &c.); (2) disorder of cerebral circulation (heart-block, anæmia, &c.); (3) disorder of cerebro-spinal fluid (hydrocephalus).

5. *Mechanism of Production of the Epileptic Seizure.*

The information garnered from the preceding sections could be summarised as implying the existence of three or four determinants for the production of epileptic phenomena.

1. *Mechanical Determinant.*—It had for many years been suspected, and often argued, that some connexion existed between the epileptic state and increase in amount and pressure of cerebro-spinal fluid; and the view had often been expressed that a relation could be established between the occurrence of the latter and failure in fluid absorption owing to arachnitis or other pathological local condition. Dandy, Fay, and Foerster had shown the existence of enlarged subarachnoid spaces more especially over the vertex and fronto-parietal regions; while, pathologically, subarachnoid collections of fluid, local œdemas, and such-like conditions had often been seen. Fay had recently added to our knowledge of this particular mechanism by his examination of the Pacchionian bodies in chronic epileptic brains, and had found various stages of sclerosis, calcification, atrophy, failure of development, and other abnormalities in these organs in epileptic subjects.

2. *Vascular Determinant.*—The consensus of opinion held that cerebral and general pallor or anæmia was more or less constantly visible to the eye just as the seizure commenced. This circulatory derangement or disorder was confirmed by the frequent observation of failure of the peripheral pulse at the outset, and the rarer one of constriction of retinal arteries at the

same moment. In 1903 the circulatory steps were epitomised by Hare as follows: (1) vasoconstriction; (2) cardiac inhibition (vagal); (3) sudden cerebral anæmia, causing unconsciousness and tonic spasm; (4) recommencement of the heart-beat causing rise of pressure, returning cerebral circulation, relaxation of tonic spasm, and clonic convulsions; (5) Re-establishment of blood pressure and cerebral circulation; cessation of convulsions. What was the proximate cause of the sudden initial vascular constriction? And where did it start? To the former question no satisfactory answer was as yet forthcoming. We did not know whether the vasomotor change began in the vasomotor centre of the bulb, or locally in the cerebral cortex, or distally, by way of reflex influence on the medulla or cortex.

3. *Humoral Determinant.*—The humoral or physiochemical determinant had received an immense amount of attention in recent times. Briefly, it must be considered as established that a number of conditions (hyperventilation, injections of various chemical substances, anoxæmia variously produced) caused experimentally a marked fall of O_2 tension in the tissues and were calculated to give rise to convulsions. "Contraction of cerebral vessels" remained unexplained. Lennox and Cobb, it was satisfactory to observe, were aware of the hiatus, for they admitted that "these processes are only contributory; they may be effective only in persons with a tendency to seizures, and with those having some pathology either in the brain, the body, or the emotional life."

4. *Neuronic Determinant.*—We were, therefore, brought back to the position which for some was still unassailed, that the essence of all epileptic semiology, major or minor, pre-seizure or post-seizure, psychical or visceral, was neuronic derangement, and that this derangement was of neuronic derivation. Nervous tissue could be, and was often enough, influenced by mechanical, vascular, and humoral agencies; but the secret of epilepsy—the core of the problem—resided in the qualities of the neural mechanisms exhibiting discharge.

The following considerations must be given due weight:—

1. The action of convulsants such as absinthe, producing fits in a normal animal, was much facilitated if the animal underwent any cerebral injury.
2. Single humoral or vascular factors, by themselves, were often insufficient to produce fits.
3. Only a small percentage of cases with head injuries and with histories of infective and other conditions reacted with fits.
4. The development of epilepsy in some organic brain states was in favour of a neural factor, seeing that no evidence of vascular or humoral anomalies was forthcoming in them.
5. A "susceptibility" or "tendency" could scarcely be ruled out in cases of direct heredity and of epilepsy in homologous twins.
6. The clinical occurrence of so-called reflex epilepsy strongly suggested a pure neural reaction.

It was therefore impossible to find one single common factor for the totality of epileptic manifestations, unless the significance of some inherent nervous factor, some functional propensity, was allowed. The only trouble was that at present we could not gauge "susceptibility" by reference to objective criteria.

6. *Influence on Epileptic Semiology of Other Intercurrent Affections.*

This, perhaps, deserved more attention than had hitherto been accorded it. As long ago as 1882 it was noticed by Bourneville and Bonnaire during an epidemic of measles in epileptics and idiots at the Bicêtre that while the intercurrent affection lasted fits were much decreased in force and frequency, and similar observations were recorded by Seglas.

So far as Dr. Wilson had discovered no attempt had been made by Gowers or any of the other authors mentioned to explain the way in which this influence may be, theoretically, exerted. According to Hare, however, it was the pyrexia which was of significance, for it involved general vascular relaxation, and he argued that vasodilatation was similarly of value in cutting short attacks of both asthma and migraine. Whatever the explanation, it might yet turn out to be of importance from a pathogenic and a therapeutic standpoint that epileptic manifestations were sometimes controlled by Nature's own methods.

Myoclonic and Traumatic Epilepsy.

Dr. J. J. L. MUSKENS (Amsterdam) considered that it was possible to recognise at least two definite clinical entities among the many forms and variations that epilepsy might present.

1. *Myoclonic Epilepsy.*—The condition of myoclonic epilepsy consisted of the syndrome of headache, myoclonic jerks, and myoclonic fits—i.e., fits tantamount to genuine epileptic fits—whether these symptoms appeared in rapid succession or only after a lapse of years. In some cases headache might be the only symptom followed after some years, as many as ten, by myoclonic jerks, while again, after a lapse of years, "fits" appeared. In some cases the development of the complete clinical picture was more rapid, while in others the symptoms were not all present or varied greatly in severity. It was not until work involving the experimental administration of drugs such as camphor bromide demonstrated in the cat and the dog the close relationship between the tactile and acoustic myoclonic reflex and the complete epileptic fit. In the lower animals, as in man, the myoclonic jerks and epileptic fits merged into one another, while in both there appeared the same time of selection for the appearance of fits—viz., the time of transition from sleep to wakefulness, or from wakefulness to sleep. Among some 3000 epileptics Dr. Muskens had found several cases in which simple syncope was frequent just before the appearance of the fit, and transitional states between syncope and seizure were occasionally met with.

2. *Traumatic Epilepsy in Civilian Practice.*—From this class were excluded all cases in which there was merely a history of head injury but tangible trace of such either on X ray examination or as shown by the presence of a scar. Parents and friends often recalled some head injury in an endeavour to account for the seizures. Probably only 1 in every 200 cases of epilepsy was an instance of true traumatic epilepsy. In myoclonic epilepsy of long standing the motor cortex became hyperexcitable and even in traumatic epilepsy symptoms of the "genuine" disorder (e.g., myoclonic jerks) might develop. An important question was the type of patient that developed traumatic epilepsy after a cranial injury. From a careful analysis of cases, Dr. Muskens considered that persons suffering from gastro-intestinal disturbances had a predisposition to epilepsy. The arrest of fits he believed to depend mainly on the combination of general or hygienic treatment in "genuine" epilepsy with appropriate surgical treatment in traumatic epilepsy. Exact and careful regulation of life as regards food, drink, exercise, rest, fresh air, and habit of life was necessary; and care must be taken to avoid gastro-intestinal disturbance, especially constipation. Dr. Muskens desired to protest against the custom of classifying epileptics as (1) those who reacted to luminal or bromide, and (2) those who did not. Early and incipient cases, he considered, should not be given drugs as in many cases the disorder might be checked by a definite and exact hygienic mode of life.

Epilepsy a Cerebral Disease.

Dr. Gordon Holmes (London) regretted the selection of the title "epilepsies," as he considered that the same pathological basis underlay all types of epilepsy. Epilepsy was essentially a cerebral disease and the main factor was a liability of the grey matter of the brain to discharge or react by an epileptic seizure under the influence of physiological or pathological factors. The view that epilepsy was merely a "metabolic dyscrasia" was, he considered, an hypothesis unsupported by any scientific demonstration. The absence of anatomical changes causally related to epilepsy was one of the main difficulties in understanding its nature, but the work of Foerster, Penfield, Fay, and others on the nature of local lesions that produced epileptic seizures promised to throw light on its pathology. On the other hand, it must not be forgotten that an organ might be normal in structure and abnormal in function. The most promising approach was through the systematic study of Jacksonian or local epilepsy. The positive and negative phenomena observed in local epilepsy might be seen in both the major and minor forms of the so-called idiopathic disease. Was the occurrence of the actual attack related to any definite cause? Probably the most important of these were the metabolic changes referred to by Dr. Wilson, but as far as he (Dr. Holmes) could see, the only trustworthy results were those of Lennox and Cobb—that alkalosis, anoxæmia, and excessive hydration predisposed to attacks, but they played probably only a subsidiary part by influencing the nutrition and functional activity of nervous elements predisposed to epileptic discharge.

Experimental Investigations with Thujone.

Dr. W. **RUSSELL BRAIN** (London) described certain experimental investigations with thujone—the convulsant constituent of absinthe—that he had carried *out it conjunction* with Dr. Riddoch. The thujone convulsion in the normal cat was a stereotyped reaction, with loss of consciousness, tonic and clonic elements, and involuntary micturition broods resembling an epileptic attack in man. In cats with a localised unilateral cortical lesion produced by cauterisation, the most striking feature of the thujone convulsion was a loss or reduction of the clonic element upon that side of the body opposite to the cortical lesion. The convulsions seen in the animal deprived of both cerebral hemispheres (the thalamus preparation) differed strikingly from those of the intact animal. Instead of clonic and tonic elements, there was seen a predominance of locomotor activity—running, crawling, and leaping associated with vigorous righting reactions. In the "decerebrate animal" (the upper portion of the mid-brain being removed as well as the cerebral hemispheres) the fits were predominantly tonic or postural in character, the commonest being an intensification of the prevailing extensor hypertonia. When the entire nervous system except the spinal cord was removed, the fits consisted of a riot of spinal activities—stepping, scratching, and excretory postures and movements following each other in rapid succession. When the spinal cord itself was transected in the dorsal reflex, the only response in the hind legs was increased reflex activity.

Dr. Brain regarded the majority of epileptics as possessing a constitutional predisposition to convulsions and many also exhibited a cerebral lesion which acted as a trigger to the charge. At one extreme there were *doubtless cerebral lesions gross enough to* cause convulsions in normal persons, and at the other a constitutional predisposition so marked that no trigger was required. Certain facts were accumulating regarding the hypothetical predisposition. Dr. Brain thought that the following facts were established: (1) The average blood cholesterol was lower in epileptics than in normal persons. (2) It was exceptionally low during status epilepticus and serial epilepsy. (3) It tended to be unstable in the neighbourhood of a fit. (4) In a number of cases it had been observed to precede a fit. There was also considerable evidence of some form of liver deficiency in epilepsy.

Three Classes of Epileptics.

Dr. **DONALD CORE** (Manchester) distinguished three classes of epileptic patients: (1) Persons otherwise normal who were liable to have isolated fits that symptomatically were epileptic. Such patient might never have more than one or two such attacks even in the entire absence of treatment. (2) Emotionally uncontrolled, nervous, worrying, introspective young men, patients who were continually on the verge of hyperthyroidism with its associated vasomotor instability. In these individuals the attacks were liable to occur in more or less well-defined settings—after trivial illness, slight accidents, periods of psychical stress, &c. They worried over their attacks and often enough in the free intervals they were more troubled by their non-epileptic psychical symptoms. (3) Those who showed no impairment of emotional control but rather tended towards mental dullness which varied from slight stupidity to a definite dementia. These patients were not worried by their condition unless the attacks were unusually frequent and there may be a family history of epilepsy. From the standpoint of treatment these three groups were poles apart, and what might be a proper line to follow in one might be disastrous in the others.

The first group required no treatment at all and the less they were brought into a medical atmosphere the better. Those of the second group required emphatic reassurance that the occasional occurrence of an epileptic attack had in their case no serious significance. As far as possible they should have their thoughts directed to the morbid effect of worry in their lives rather than the effect of the attacks. They should be encouraged to live their customary lives and to avoid any restriction of their pleasures and enjoyments. Such sedative treatment as might be prescribed need not be continued for any length of time. To a certain extent the same principles of treatment applied to the third group of cases but in these drug treatment was of greater though not of the greatest importance. The most important element of treatment was to prevent the patient from looking upon himself as an outcast. If the mental dullness was such as to prevent even the semblance of a useful life in home surroundings, then he should be sent into an epileptic colony where it was normal to be epileptic and where he had a certain definite routine of life.

The Emotional Factor.

Dr. E. L. **FOX** (Plymouth) mentioned the importance of recognising the psychogenic origin of idiopathic epilepsy; he considered that in studying the history of cases of epilepsy the close analogy of the emotional characteristics of the epileptic with those of the hysteric was almost invariably forthcoming. He instanced cases in which repression was apparently an important factor in the causation of epilepsy and in which the attacks ceased on the repressed incident being recalled. Dr. Fox advocated the endeavour to raise the level of the emotional standards in all epileptics so that they could more readily resist the attacks.

Sphenoidal Sinusitis and Epilepsy.

Dr. F. A. **PICKWORTH** (Birmingham) demonstrated slides of a series of four cases of epilepsy of differing duration, all of which showed evidences of sphenoidal sinusitis and *infection of the pituitary gland.* He drew attention to the large proportion of epileptics in mental hospitals, and brought forward evidence indicating that epilepsy, as well as insanity, might be due (1) to an extension of sepsis from an infected sphenoidal sinus along the course of the carotid artery producing the minute focal areas of brain necrosis found in epileptics, and (2) extension through the pituitary gland to the area of the brain immediately above it which subserves vital metabolic processes especially affected in epilepsy. He emphasised the necessity of a careful examination, hitherto much neglected, of the sphenoidal sinus and pituitary gland in necropsies of epileptics.

Diet in Epilepsy.

Dr. **TYLOR FOX** (Lingfield) briefly outlined his experience of the ketogenic diet in five cases of epilepsy. He had found this, as had American observers, to be most effective in cases of petit mal.

He expressed the hope that others who were experimenting with the diet would publish their results.

Dr. A. MACDOUGALL (Manchester) spoke of his experiences at the David Lewis Epileptic Colony as regards the general character and temperament of epileptics.

The PRESIDENT referred to the well-known influence of intercurrent maladies on epilepsy, especially the amelioration, suspension, and even cessation of seizures following measles and other diseases. If the cardinal factor in the pathology of epilepsy was an instability of the cerebral neurones, then the cessation of fits indicated that the neural mechanisms had become more stable. It seemed probable that such restoration was the result of biochemical changes rather than of vascular or other extraneural factors. Following this line of thought—viz., that there was present a perverted metabolism—the question of diet needed further investigation. Various diets had been tried and the beneficial effect of fasting in some cases had led to the adoption of a ketogenic diet. Dr. Bury had been much impressed by the results of the lævulose-tolerance test in epilepsy—indicating some definite liver deficiency, and also by the investigations on blood cholesterol. Reflecting on the pathological changes in the liver in pernicious anæmia and the wonderful results of liver treatment in that disease, the President ventured to suggest that it would be worth while supplementing the diet of epileptic patients with minced liver.

SECTION OF VENEREAL DISEASE.

LESIONS OF LATENT SYPHILIS.

Colonel W. COATES, *President of the Section*, opened the session with an address on the history of venereal disease, and the ideals which were to be aimed at in modern treatment. The section was then addressed by Prof. A. S. WARTHIN (Michigan). He said he had made a study dating from 1906 of the histological lesions of latent syphilis in relation to the presence in these lesions of the *Spirochæta pallida*. He first used the Levaditi method of staining, but later, with the aid of Dr. Starry, he perfected the Warthin-Starry method which reduced the time of staining and resulted in a greater percentage of positive spirochæte findings. His material was derived from necropsies conducted on patients drawn from the whole State of Michigan, who were chiefly of the lower middle classes in the small towns and rural districts. The percentage of syphilis in this material he found to be very high, varying in different years from 30 to 60 per cent.

According to Prof. Warthin's observations, in the *leptomeninges* the lesions of latent syphilis occur very frequently, though varying in intensity, and are usually found over the sulci of the parietal and frontal lobes. The more active lesions show localised areas of a mild proliferative process with slight infiltration of monocytes, plasma, and lymphoid cells, the milder lesions being of a more sharply localised character. Every stage of severity is found from the slight fibrosis of the meninges to the typical form of syphilitic meningitis. In the brain localised perivascular infiltrations occur, mostly in the frontal and parietal lobes; they are usually few in number and vary in intensity. Otherwise it may be said that the latent syphilitic has lesions identical with those of the paretic. In both the meninges and the brain the incidence of these lesions is greater in the male than in the female.

In Prof. Warthin's experience the *heart* of every male latent syphilitic shows latent lesions varying from small areas of infiltration to the more diffuse areas of interstitial myocarditis. Though the incidence of these cardiac lesions of latent syphilis in women is small, in some women the more severe forms of syphilitic myocarditis do occur. The part of the heart usually involved in latent syphilis is the septum and the anterior and posterior walls of the left ventricle, near the apex. The lesions are intramuscular rather than perivascular and of a diffuse character. A characteristic feature is the increase of nuclei beneath the endocardium, the cells lying in two to five rows closely crowded together. Œdema of the stroma is found, being the more marked with the more active lesions. Fibrosis of the stroma results, with fatty degeneration and atrophy of the muscle fibres, though between the patches of infiltration hypertrophic muscle fibres are often seen. The aortic valve alone is commonly involved, and this through the vasa vasorum. Macroscopically, the heart of the latent syphilitic usually shows dilatation of the left or both ventricles; there is usually no valvular lesion, except in younger subjects in whom latent syphilis appears to predispose to bacterial endocarditis. In life these cases of latent cardiac syphilis show signs of myocardial insufficiency, and the common clinical diagnosis is that of "rheumatic heart." The condition is progressive and cardiac death is frequent in the male.

Latent active lesions are to be found in the *aorta* of all male, and in the majority of female, syphilitics. The lesion is essentially a disease of the vasa vasorum, which become thickened and obliterated; the term "mesaortitis" is a misnomer. This results in a slow infarction of the intima and part of the media, with sclerosis and atrophy of the muscle and degeneration of the elastic tissue. The syphilitic character of these lesions can only be determined by microscopical examination. Syphilis of the aorta exists in three forms: with aneurysm, with aortic insufficiency, and with lesions of the vasa vasorum alone. The latter is the most common; it may be symptomless, or give the syndromes of aortalgia, or even angina pectoris. Aneurysms are generally produced by local weakening of the walls due to miliary gummata along the vasa vasorum. Spirochætes in small groups can be demonstrated by the improved starch-gelatin modification of the Warthin-Starry method.

In both sexes the *liver* is usually the seat of latent syphilitic lesions. They consist of infiltrations of the periportal tissue, leading to fibrosis and some hepatitis. All stages of severity exist up to the severest form of cirrhosis (hepar lobatum), which latter condition is more frequent in women than in men. The percentage of liver involvement appears to be on the increase, particularly in the cases which have received modern arsenical treatment. Spirochætes are more difficult to demonstrate in the liver than in any other organ, usually being found only in small numbers and in the active areas of infiltration.

Lesions of latent syphilis are common in the *pancreas* though usually mild; they take the form of an interstitial pancreatitis not arising from the ducts. The intralobular stroma is increased and the islands may become fibroid. He has found this condition the most common cause of diabetes in his diabetic cases.

In the *adrenals* latent syphilitic lesions are more severe in women than in men. In the majority of cases they do not produce signs of adrenal insufficiency, yet they may be severe enough to cause marked atrophy and fibrosis, giving a typical clinical picture of Addison's disease. The spirochætes are easily shown in the cellular infiltrations, but in small numbers.

The *testis* of every latent syphilitic shows sooner or later patches of interstitial orchitis, with atrophy of the germinal epithelium and fibrosis of the basement membrane of the tubules. An early loss of spermatogenetic function occurs in the majority of cases.

Prof. Warthin has never found a syphilitic lesion in either the *ovaries* or the *Fallopian tubes*. The spirochæte has been demonstrated in the ovary in congenital, but never in acquired, syphilis. This suggests a local tissue immunity of the organ. Lesions have been found in the endometrium of the *uterus*, extending into the uterine wall.

It is true, he said, that the latent syphilitic presents a high percentage of *pulmonary fibrosis*. Only rarely, however, can the spirochæte be demonstrated or gummata shown to be present. He had only encountered 15 cases in which the presence of pulmonary syphilis was positively proved, the majority of these cases being associated with gummatous lesions, the remainder being cases of Ayerza's disease.

In conclusion, Prof. Warthin pointed out that the lesion of latent syphilis repeats the essential pathology of the hard chancre and of the secondary and tertiary lesions of active syphilis, being predominantly vascular and perivascular, and the infiltrations being derived from the proliferation of cells in situ. He had never seen at necropsy a case of perfectly healed syphilis, a statement which was as true of cases treated in the modern manner as of cases treated by the old mercurial method; the more evident difference was the greater frequency of chronic hepatitis in cases treated by the arsenical method. What the treatment did accomplish in either case was the more rapid reduction of the average active case to a state of latency. The latency of the infection might last throughout the individual's life or at any time exacerbations might take place, and the disease rise above the clinical horizon; what determines these exacerbations was yet to be learnt. Whether a five years' period of treatment would finally rid the body of spirochætes he could not say, for no more than three years' treatment had been given to the cases from which he derived his material.

Discussion.

The discussion was opened by Sir HUMPHRY ROLLESTON, who commented on the magnificent slides which Dr. Warthin had exhibited. He asked whether the spirochætes in the slides had been proved to be the *S. pallida*. The incidence of latent syphilis would appear to be very high. Could a patient never be deemed free from syphilis until the pathologist's verdict at necropsy had been obtained? If both early and late treatment were given, could not these cases be prevented from becoming latent? What was the relation of the Wassermann reaction to latent syphilis?

Colonel L. W. HARRISON appealed for a more optimistic view than that presented by Prof. Warthin. He wondered if Dr. Warthin's cases were drawn from a highly syphilised population where old methods of treatment had been in vogue. He could not agree that the arsenical preparations were merely immunising agents; he considered them to be definitely spirochæticidal, as instanced by the rapid disappearance of certain specific lesions after even one dose of intravenous arsenic. He further understood that tissue transplantation from infected animals after they had received early arsenical treatment did not transmit the disease. He was strongly of the opinion that arsenobenzol was useful in the treatment of cardiovascular lesions, when it was skilfully exhibited.

Prof. G. LORRAIN SMITH asked whether Dr. Warthin had examined the skeletal muscles of his cases. Did the *S. pallida* act on the organism by means of a toxin or by the effects of local tissue reaction—for example, the perivascular changes?

Dr. DAVID NABARRO said that in 14 years at Great Ormond-street he had decided that the diagnosis of congenital syphilis was by no means simple. The signs were often latent, and diagnosis was particularly difficult after the first few weeks of life. He gave a comprehensive review of the clinical manifestations of congenital syphilis and showed X ray pictures revealing abnormalities in the skeleton which were not otherwise apparent.

Dr. DAVID LEES asked whether Prof. Warthin had examined any cases which had been treated with malaria. He agreed with Colonel Harrison that cardiac conditions benefited from careful treatment with arsenobenzol. Could Dr. Warthin explain the absence of the *S. pallida* in the ovaries and the tubes? He had observed that a positive W.R. generally became negative with the onset of the menopause. He further asked whether the *S. pallida* were alive or moribund in the sections which had been shown.

Dr. E. TYTLER BURKE thought that the results obtained by Dr. Warthin might be due to incomplete treatment. He was not satisfied that there had been early and persistent treatment. He thought that the amount of syphilis in this country was greatly underestimated; he put in a plea for the more adequate teaching of venereology in the medical schools and among post-graduates.

Dr. H. M. HANSCHELL stated that he had been staining slides by the Levaditi method and had found them unsatisfactory. In his experience syphilitics did not complain of early loss of sexual desire. He suggested that the word "*fenced*" be used instead of *latent* or *dormant*, indicating that the *S. pallida* in these cases was fenced by fibrosis from the drug. He recommended excision of the primary lesion (and even in some cases of accessible indurated lymphatic glands) where the condition did not clear up readily under the influence of arsenobenzol. He could not too strongly emphasise the importance of early and thorough treatment.

The PRESIDENT, in calling upon Prof. Warthin to reply, said that he had been reluctant to admit that cases of second primary infections could occur, though he had had cases which strongly suggested this phenomenon. Many years ago he had practised excision of the primary chancre, but he had come to the conclusion that this had no influence on the course of the disease.

Reply.

Prof. WARTHIN, in reply, stated that the spirochætes in question had been inoculated into rabbits with the production of typical syphilitic lesions. He reiterated that in all of his cases he had never seen a complete cure; there were latent lesions in all of them. Latent syphilis was really a high grade immunity. He concurred with the contention that arsenobenzol was spirochæticidal, but he would emphasise that its practical effect, along with other antisyphilitic remedies, was the production of immunity. He considered that a strongly positive W.R. indicated active syphilis, with certain exceptions, such as widespread malignant disease, chicken-pox, and miliary T.B. He considered that a negative W.R. was of no value whatever. He could not agree with Col. Harrison that he was a pessimist. He admitted that his cases were drawn from a highly syphilised community, but many of his cases had been treated for three years according to modern methods. He considered that it would only be useful to treat early cardiovascular conditions with arsenobenzol, since old lesions could not be cured. He had not examined the skeletal muscles of his cases. He believed that the *S. pallida* acted by local tissue reaction rather than by a toxin. He could not explain the local tissue immunity of the ovaries and tubes, though many theories had been put forward. To Dr. Lees he replied that a moribund spirochæte was always fragmentary. He did not think that extirpation of the primary chancre could make any difference to the progress of the disease. With reference to second primary infections, it was to be remembered that animals becoming immune to one strain of *S. pallida* could be infected with another strain. It was highly probable that the same results obtained in human beings.

A number of microscopical slides prepared by Prof. Warthin were open for inspection in the Pathological Museum.

SECTION OF ANÆSTHETICS.

Dr. A. L. FLEMMING (Bristol) presiding, Dr. H. P. FAIRLIE (Glasgow) read a paper on

Ethylene and Oxygen Anæsthesia.

He said that the proportion of ethylene gas to oxygen was usually about 88 per cent. ethylene to 12 per cent. oxygen, but varied according to the age and build of the patient, the condition of heart and lungs, and the nature of the operation, the oxygen percentage always being maintained at such a level as would prevent respiratory failure; more than a slight degree of cyanosis was regarded as a danger sign. If this point was remembered the anæsthetic was perfectly safe. Dr. Fairlie himself arranged for re-breathing, using the same apparatus for ethylene administration as for nitrous oxide and oxygen. As far as safety, rapid action, and immunity from ill effects were concerned ethylene and oxygen anæsthesia resembled nitrous oxide and oxygen. There were, however, two points of difference, the first being favourable to ethylene in that a deeper anæsthesia was obtained. In Dr. Fairlie's experience some cases did better with ethylene and oxygen anæsthesia than with a nitrous oxide anæsthesia. The second difference was the very disagreeable smell of ethylene gas, which affected the other occupants of the operating theatre more than the patient. He was in the habit of having his gas made up with oil of eucalyptus and had never had any complaints from the patient.

Dr. Fairlie reviewed the advantages of ethylene from the points of view of the patient, the surgeon, and the anæsthetist. The patient did not experience disagreeable sensations; he lost consciousness rapidly without showing resentment or excitement, and though vomiting occurred in about 75 per cent. of cases it was within a minute or two of the end of the administration. No unpleasant taste remained. The surgeon was satisfied with the anæsthetic in all cases except those in which much relaxation was required. The anæsthetist was provided with a safe anæsthetic with a large margin of safety, and had ample warning of any impending danger. Dr. Fairlie alluded to the inflammability of ethylene gas and the precautions necessary in using it.

The PRESIDENT asked for information on the margin of safety.

Dr. K. B. PINSON (Manchester) in his dental work had found ethylene successful in some patients where nitrous oxide had failed, and had been disappointed in the results in other patients. He advocated the use of ethylene in old and feeble patients and in those who were very ill. He suggested that its safety was due to the amount of oxygen employed, and did not consider the smell a contra-indication.

Dr. C. F. HADFIELD (London) referred to the work of Prof. H. B. Dixon and the intense importance to the anæsthetist of the flash point and ignition point of gases. The smell of ethylene gas was not due to impurities.

Dr. H. E. G. BOYLE (London) read a paper on

Gas and Oxygen in Midwifery.

He said that he had always regarded chloroform as a dangerous and toxic drug to give a woman at childbirth, and stressed the advantages of nitrous oxide and oxygen anæsthesia, which had been made familiar to him by Dr. Wesley Bourne of Montreal. He said that the patient was given nitrous oxide and oxygen with every pain and learned to ask for the mask, since the anæsthetic diminished the pain. Owing to the fact that the gas was non-toxic it could be given for a long time without harm to mother and child provided there was no cyanosis. The anæsthetist could greatly reduce the work of the obstetrician, since he need not send for him until about one hour before the child was born. Another advantage was that the patient could be completely anæsthetised if ether was added when the head was on the perineum; when the head was born the gas and ether were shut off and carbon dioxide and oxygen (1 in 6) given, with the result that the mother's respiration was increased and the child became a rosy pink and "gave tongue." The anæsthesia could be deepened again for the delivery of the placenta. Patients in his experience recovered consciousness very quickly. He cited as disadvantages the fact that a special anæsthetist who was familiar with the method had to be present, and that special apparatus had to be used; for these reasons also the cost was greater. His impression was that the pains were not slowed but were rather increased in frequency and in strength where plenty of oxygen was used, and patients were certainly less exhausted and recovered more quickly than when choloroform was used. He emphasised the importance of avoiding cyanosis.

In the discussion that followed Dr. R. C. MOTT (Burslem) said that he saw no objection to giving gas and oxygen throughout the labour. Dr. E. F. HILL (Manchester) objected to the method on the score of expense and suggested that labour pains should be mitigated by means of chloroform given with a Vernon-Harcourt inhaler.

Dr. F. P. DE CAUX (London) then read a contribution on

Glucose—Why, When, and How to use it.

as an antidote to the shock of operation and anæsthesia. He described the mechanism of its working according to Mr. J. McDonagh's theories. He advised the use of 15 to 20 units of insulin two hours after the injection of glucose.

He recommended that glucose should be given before a severe operation, when liver efficiency was suspected, when the basal metabolic rate was high, as in Graves's disease, and when the patient was emaciated or under-nourished. Glucose should always be given after operation when a blood transfusion was impossible and after any anæsthetic where the patient showed signs of shock; where glucose had not been given before; where the surgical manipulation had been rough; when more anæsthetic had been used than usual; and when there was a history of epilepsy.

A discussion followed in which Dr. FAIRLIE, Dr. HILL, and Dr. MOTT took part.

Dr. WINIFRED WOOD (Edinburgh) read a paper on

Rectal Ether Oil Anaesthesia, with Special Reference to Brain Surgery.

She had used in over 70 cases a modification of the technique devised by Dr. J. T. Gwathmey of New York, who had closely investigated the properties and the action of ether in oil. The safety of this type of anæsthesia was the reason for its employment in cases of bad surgical risk and she cited certain operations in which it had been chosen. She pointed out its application to severe and prolonged operations in brain surgery. The method had three advantages in brain surgery: (1) access to the patient's face was not necessary; (2) the dose of ether was smaller than in an inhalation anæsthesia; (3) by reason of the sleep-like quality of the anæsthesia the administrator was free to take observations on blood pressure, pulse, and respiration, which formed a valuable guide to the condition of the patient and to how far operation might proceed. She gave a brief account of the technique employed, pointing out that the procedure in general surgery and brain surgery was different owing to the fact that morphia was strongly contra-indicated in the latter. The anæsthesia produced by rectal ether was very light and might have to be supplemented by inhalation ether vapour in certain cases.

Dr. Wood discussed the action of rectal ether from the physiological aspect, referring to its slight effect on blood pressure even after many hours administration, and the relative absence of disturbance of the acid-base balance. Difficulties might arise from the pre-existing intracranial tension and the hæmorrhage during operation. With this type of anæsthesia there was generally a good convalescence with none of the complications usually ascribed to the anæsthetic. The long period of sleep after operation was an asset. Notes of brain operations on middle-aged and elderly patients which lasted from three and a half to six and a half hours were given to show the satisfactory condition of the patient during and after operation, even when hæmorrhage was so severe as to necessitate blood transfusion on the table.

Dr. S. THOMSON ROWLING (Leeds) read a paper on the

Scientific Administration of Anæsthetics

and demonstrated his modification of Clover's inhaler, along with the anæsthetic table which is designed to supply oxygen, nitrous oxide, and carbon dioxide in any percentage combination with or without chloroform vapour of definite strength. Describing the nervous, circulatory, and respiratory depressions that arise from anoxæmia, and in which apnœa plays a part, he stressed the importance of the use of oxygen and carbon dioxide together during an anæsthetic. He believed that all dangers of anæsthesia, operative and post-operative, could be prevented by the administration of an anæsthetic with this apparatus, which provided for a percentage of ether, oxygen, and carbon dioxide according to the patients' requirements. Dr. Rowling quoted cases to show the good results obtained.

Reviews and Notices of Books.

RECENT ADVANCES IN PULMONARY TUBERCULOSIS.

By L. S. T. BURRELL, M.A., M.D. Cantab., F.R.C.P. Lond., Senior Physician to the Royal Free Hospital; Physician to Brompton Hospital for Consumption and Diseases of the Chest. London: J. and A. Churchill. 1929. Pp. 217. 12*s.* 6*d.*

IN the preface of his book Dr. Burrell states that he has "tried to describe the recent increase in our knowledge of tuberculosis, and to separate the real advances in treatment from those methods which have no scientific basis, and enjoy but brief, though occasionally recurrent, phases of popularity." In this attempt he has been most successful, and his book will be read with profit not alone by those who are specially interested in diseases of the chest. It is illuminated throughout by a common sense not always exhibited by those who write on tuberculosis, and this is a virtue which will be appreciated by the general practitioner. In discussing scientific theories, Dr. Burrell knows how to compress his matter without losing the interest of his reader, and his explanations are always lucid. A chapter on radiology is illustrated by a series of skiagrams provided by Dr. Stanley Melville. These are well produced and should demonstrate the supreme value of this means of diagnosis to those whose opportunities for studying radiograms are limited. Seven of the 12 chapters are devoted to the treatment of pulmonary tuberculosis and its complications. Adequate nourishment, rest, and fresh air remain the most generally effective methods for combating the disease, and Dr. Burrell's grasp of essentials is well illustrated in his references to these. Modern methods of treatment are designed to supplement and not to supersede treatment on sanatorium lines. The uses and limitations of sanocrysin are well summarised in a short chapter which is followed by one fully describing artificial pneumothorax. In the next edition of the book the sections on operative treatment by thoracoplasty and other surgical methods might be expanded, since recent advances in thoracic surgery are noteworthy.

HANDBOOK OF PHYSIOLOGY.

Eighteenth edition. By W. D. HALLIBURTON, M.D., LL.D., F.R.C.P., F.R.S., and R. J. S. McDOWALL, M.B., D.Sc., F.R.C.P. Ed. London: John Murray. Pp. 902. 18*s.*

THOUGH the young medical student may be content to borrow from a library a large tome on anatomy and supplement it by short dissecting manuals, he usually buys his first text-book of physiology. It is therefore this work which he opens eagerly in the first evenings of October, feeling that by getting ahead of his lectures he can prepare himself to enjoy them and to take notice rather than notes of the spoken instruction. It must be confessed that his first reaction is generally one of disappointment. In the elementary form in which they are presented to the medical student, chemistry, physics, and biology seem fairly concrete and established sciences. Of the gross and minute structure of the body, too, more is apparently known with precision than he can ever hope to acquire in two years' of study. In physiology, however, when he seeks information on subjects which may interest him—for example, the meaning of sleep, the exact functions of the liver which are deranged in a "bilious attack," the mechanism of secretion of urine—he finds that these phenomena are still largely in the realm of theory. He begins to wonder how he is going to grapple with the subject, for there is nothing more difficult to remember, and especially to reproduce, than an argument involving the examination of many theories mutually contradictory and each founded on experiments which in themselves seem reasonably conclusive. It is no wonder that the student turns to the dissecting room for relief, though the relief may change to despair when he persistently fails to discover those cutaneous nerves which in the pictures protrude so convincingly through the superficial fascia. He has to learn that his days of simple acceptance of facts imparted by a teacher are over and his duty henceforward will be critically to examine and then to assimilate such knowledge as has been gained painfully by observation and experiment. It is largely through the medium of his first text-book that his attitude to physiology and ultimately to medicine will be formed, and to strike the mean between too much simplification, which will only postpone the difficulties, and too much complexity, has been the task successfully accomplished during many years of active teaching by Prof. Halliburton. It is thus a pleasure to see that this Handbook of Physiology has been reissued after four years in a renewed form. In the preparation of this eighteenth edition Prof. Halliburton has had the collaboration of Prof. McDowall who succeeded him in the chair of physiology at King's College, London. Prof. McDowall has contributed several new chapters and has rewritten others. That on the nervous system has been brought up to date and an account of postural and conditioned reflexes has been included. Sections on the autonomic nervous system, speech, the control of the circulation, carriage of carbon dioxide, maintenance of body neutrality, the vitamins, ductless glands, and intermediate metabolism are also for the most part new, while recent work on the formation of blood and the bile, on the spleen, on the control of respiration, and on test-meals, has been added. To admit all this new material anatomical detail has been reduced, but essential anatomy and histology are retained. There are now more good text-books of physiology than there were 30 years ago when Prof. Halliburton first took charge of a work which had maintained its vitality for half a century, since it originally appeared in 1848 as Kirkes's Physiology. We seen no reason why this edition should not be as popular as its many predecessors, and we trust that Prof. Halliburton's name may for long be associated with its further progress.

AMERICAN CHEMICAL SOCIETY MONOGRAPHS.

Thyroxine. By EDWARD C. KENDALL, M.S., Ph.D., D.Sc. The Mayo Foundation, Rochester, Minnesota. New York: The Chemical Catalog Company, Inc. 1929. Pp. 265. $5.50.

Biochemistry of the Amino-Acids. By H. H. MITCHELL, Professor of Animal Nutrition, College of Agriculture, University of Illinois; and T. S. HAMILTON, Associate in Animal Nutrition of the College. Same publishers. 1929. Pp. 619. $9.50.

THE appearance of Kendall's book, which was announced some years ago, has been delayed in order that the author might first bring to a conclusion his work on the constitution of thyroxin. It is mainly concerned with the chemical nature of the thyroid gland and its secretion, and forms one of the monographs issued by the American Chemical Society. In the last few months of 1914 Dr. Kendall's persistence in pursuing a long and tedious series of researches was rewarded by the isolation of a substance [illegible]
named thyroxin. Since [illegible]
the whole gland are [illegible]
stance its isolation has

only of the internal secretions, but also of the nature and regulation of life-processes in general. Dr. Kendall says in the preface: thyroxin bridges the gap between living protoplasm and the expression of what may be called personality or temperament, and has a definite place in the study of normal and abnormal mental processes.

Since the discovery by E. Baumann in 1895 of the remarkable fact that iodine was a normal constituent of the thyroid gland, attempts have been made to find a reason for the presence of this element and to determining the chemical nature of the particular compound in which it is involved. Baumann showed that acid hydrolysis gave a substance which he called thyreo-iodin or iodothyrin, which contained a very large proportion, about 10 per cent., of iodine, and which had the same action as desiccated thyroid when given to patients suffering from either hypothyroidism or from goitre. A few years later, in 1907, Nürnberg showed that the two amino-acids, tyrosine and tryptophane, were essential constituents of iodothyrin. Nürnberg used the process of digestion with barium hydroxide in the preparation of his material, and therefore in two important points he anticipated the results which Kendall and C. R. Harington were later able to achieve. Unfortunately, Nürnberg discarded the insoluble fraction resulting from the digestion, and it was this fraction, as Kendall showed later, that contained the thyroxin. The advances made in the next few years were slight, and it was not until 1914 that Kendall's researches led to the isolation of the crystalline substance from sheeps' thyroid. The author's early experiments make fascinating reading. After three years' steady work seven grammes of the compound had been accumulated from a vast quantity of the gland substance. The crystalline structure and the physical and chemical properties were described, and several derivatives were prepared. Acting on the belief that the compound was a derivative of indole, possibly from an iodised tryptophane precursor, Kendall and Osterberg suggested a probable formula which the work of Harington during the last four years has shown to be incorrect. Great credit must be given to Kendall for the modest manner in which he refers to this work. Harington, in a series of monumental researches, has shown beyond doubt that the constitution of thyroxin is really that of an iodised derivative of tyrosine and not of indole or tryptophane. The difficulty of the problem was bound up with the presence of the iodine in the organic molecule; Harington described in 1906 how he first reduced thyroxin, thus preparing the iodine-free parent substance which was eminently suitable for chemical work. In this way it was first definitely established that the iodine free compound, and hence probably thyroxin itself, was a derivative of tyrosine. Harington then synthesised the iodine-free compound, and a year later, working with G. Barger, published the synthesis of the tetra-iodo compound and proved that this substance was chemically identical with thyroxin, and also increased the basal metabolic rate to the same extent. By a remarkable coincidence Dakin had also discovered that thyroxin may be made to yield tyrosine, but on hearing of Harington's much more complete results he withdrew his manuscript from the press.

These recent advances are of such interest that they have properly occupied a great deal of the space available of this book, though they constitute only a portion of its contents. The remainder deals adequately with the influence of the thyroid gland on hypothyroidism, on the metabolism of carbohydrate nitrogen, phosphorus and calcium and on the distribution of water, on the nervous system on growth, and on the basal metabolic rate. Other sections describe the standardisation of the hormone and its influence on amphibian metamorphosis. The concluding chapters of the book describe the relation between the histological appearance and the activity of the gland, some clinical aspects of thyroid disease, and finally the effect of thyroxin on some biological oxidations. The bibliography contains 541 references.

Prof. Mitchell's work is one of the same series of monographs. The biochemistry of the amino-acids is complicated, and the authors have set themselves a difficult task. In the first place, it is not easy to draw a line between the pure chemistry and the biochemistry of the amino-acids, and wherever an author attempts to draw this line he is liable to criticism. For instance, although in the first chapter the chemical properties of the amino-acids are described in fair detail, there is practically no indication of the synthetic work that has been done in building them up into peptides. The sketchy account of this important achievement is unsatisfactory, though admittedly an adequate presentment would have taken up much space. The next chapter, dealing with the determination of amino-acids in proteins, gives a full and critical description of all the best known methods employed, with an exhaustive review of the literature of the subject. This is followed by an equally detailed section on the individual amino-acids; a series of tables give the amino-acid content of different proteins as determined by various methods, a reference being given to each figure quoted. The fourth chapter, on the liberation of the amino-acids in the intestinal tract, is followed by three chapters devoted to amino-acid metabolism. Their specific dynamic effect is next considered, and the final chapter of the book deals with the value of proteins from the point of view of nutrition.

A fine piece of work and a valuable contribution to biochemical literature.

BOOKS FOR NURSES.

Gynæcology for Nurses. Fifth edition. By COMYNS BERKELEY, M.A., M.D., M.C. Cantab., F.R.C.P. Lond., F.R.C.S. Eng., Gynæcological and Obstetric Surgeon to the Middlesex Hospital, &c. London: Faber and Faber, Ltd. 1929. Pp. 426. *7s. 6d.*

FOR nearly twenty years this has been one of the most popular text-books for nurses in the English language. The fifth edition has been extensively revised, and in parts rewritten; the author notes that revision has been greatly aided by suggestions sent by sister tutors throughout the country. New matter has been added with reference to X rays, radium, blood transfusion, and the modern methods of treating syphilis. The book owes its popularity to its simplicity, its clearness, and its dogmatic teaching. The author never forgets that he is writing for nurses and not for medical students.

The Nurses' Handbook of Hygiene. Second edition. By L. E. H. WHITBY, M.A., M.D. Cantab., M.R.C.P. Lond., D.P.H., Assistant Pathologist, Middlesex Hospital. Same Publishers. 1929. Pp. 163. *4s. 6d.*

THE second edition of this handbook, while it occupies approximately its former bulk, has been brought up to date in most of its sections, particularly in relation to vitamins and food preservatives. It suffers from the defects common to books which attempt to cover a very wide range of subjects in an elementary fashion. For instance, ventilation is discussed at considerable length without reference to the katathermometer, although the estimation of carbon dioxide is given as a measure of ventilation; standards for metallic impurity of water are mentioned, but the importance of chlorine and ammonia is only noted in general terms. The designation "Grade A. Certified," in relation to milk, does not exist. The connexion of summer diarrhœa, diphtheria, and typhoid fever with contamination of the atmosphere of houses by sewer air would not now be generally accepted. The author's views on the milk problem are of interest; his suggestion that milk from tubercle free herds should always be boiled will not meet with general acceptance. These points are noted because, on the whole, the book is a useful guide, and nurses will find therein most of the information on hygiene which they will need for examination purposes.

THE LANCET.

LONDON: SATURDAY, SEPTEMBER 14, 1929.

A NATIONAL MATERNITY SERVICE SCHEME.

IN reviewing the vital statistics for 1928 last week we had to record that the maternal death-rate for that year (4·42 per 1000 live births) offered little scope for optimism, being the worst on record since 1911. A more hopeful outlook for the future is to be anticipated since the adoption by the British Medical Association of a scheme for a National Maternity Service which is based on sound lines and may lead to important legislation. It is proposed to utilise the services of general practitioners and midwives with as little additional machinery and institutional accommodation as possible, and it could therefore be brought into action in a reasonable period of time with the minimum dislocation of existing conditions of practice. The principles on which this scheme, which was outlined in THE LANCET of July 27th (p. 195), is based are that normal maternity cases can be safely treated at home, and that mortality and morbidity can be greatly reduced by proper care and supervision during the antenatal, natal, and postnatal periods. The cost of the scheme, calculated at £2,100,000, could be met on a compulsory national insurance basis, which would include at once all women entitled to maternity benefit; others in a similar economic position could be brought in by further administrative action, leaving only the small percentage working on their own account to come in on a voluntary basis. The additional contribution to meet the services outlined is reckoned at 0·4*d.* a week from the employer and insured person, made up to 0·9*d.* by the State. Against this could be set some saving to the State and local authorities in the shape of fees paid to doctors called in by midwives and lessened costs of clinics. A medical practitioner and midwife would be provided for all pregnant women under the insurance scheme. Antenatal care would be shared by both, the midwife keeping the patient under close supervision. The doctor would examine her at least once, determining whether her labour can be left to the midwife, and would respond to the call of the midwife throughout pregnancy, labour, and lying-in, if required. The doctor would see every patient and, if necessary, make a pelvic examination, before she returns to work. Additional material and service allowed for in the cost include payment for hospital accommodation for cases unsuited to delivery in their own homes, sterilised dressings, ambulance facilities, and another practitioner when required for consultation or administration of anæsthesia.

A system of this kind, by which attendance on the normal is left to the midwife with medical supervision and assistance in the case of abnormality, has been widely advocated as the one most likely to lead to a lower maternal death-rate. Briefly, the reasons given in support of it are that mortality is lowest in those countries where such a system prevails—e.g., Scandinavian countries, Holland, Italy; that the best results in this country are obtained under this system, as in the midwifery service of the Queen's Institute, hospital and other maternity districts; that as soon as it is recognised that the first object in midwifery is to maintain the normal throughout childbearing it is needless to use the more highly trained medical services for attendance—often prolonged—on natural labour, if a midwife with a doctor on call will suffice. The British Medical Association has now accepted this view, has brought out a scheme embodying the methods of institutional practice, and has shown how the change can be effected by improving and using in a different manner the existing machinery. That the scheme brought forward by the Council was adopted by the representative meeting with only minor emendations after a brisk discussion justifies the agitation on maternal mortality, for five years ago acceptance of the scheme now outlined would have been almost unthinkable. That there would be difficulties and disappointments in its initial stages is certain, for the results obtained in hospital districts cannot be expected at first, since institutions have a tradition behind them as well as a carefully selected and skilled personnel. Even if the patients attended by the Queen's Institute are in some degree a selected group, the results obtained by its midwives with medical aid provided by local practitioners are sufficient to show that the system of working is itself the most important factor, and one would expect that a national service of the kind envisaged by the Association's memorandum would soon approximate to the Queen's Institute figures. One question that must be left unanswered is how the insured women would behave under it. Would they demand more of the medical services than the scheme has provided for? Previous experience of women under the National Health Insurance Act suggests doubts as to the possibility of making any accurate estimate.

In a paper that appears elsewhere in this issue, Mr. GIBBERD gives figures from Guy's Hospital district which point in the same direction as those from the Queen's Institute and the institutional district practices in London, Liverpool, and Scotland, quoted in the appendix to the Association's memorandum. Though in Guy's Hospital district attendance is divided between medical students and midwives the system of working is the same. In order to make his cases an average sample of the general population and render his figures more comparable with the national, Mr. GIBBERD has included all patients domiciled in the area of the hospital, whether delivered at home or transferred to hospital. He omits, however, to draw attention to the fact that his figures are not strictly comparable to the national figures, because his are based on 1000 deliveries and the national ones on 1000 live births, and his figures exclude deaths due to early abortions and other conditions in pregnancy not falling under the ordinary work of a maternity district. These points, however, in no way invalidate his interesting comparison of the two periods under review, and he is able to show what the national returns have been unable to show, and that is a remarkable drop in the maternal death-rate. In the last ten years the rate was but a quarter of what it was sixty years ago, 1·03 in place of 4·4 per 1000 deliveries. His figures regarding the amount of interference in the two periods are of great value, though, unfortunately, those of the recent period are confined to the cases in one year only (1928) and may thus differ considerably from the average. The percentage of Cæsarean sections suggests an error that would be lessened somewhat if a greater number of years had been averaged. It works out at 1·3, the same as the total interference in the early series. Over one abdominal delivery in an average sample of 100 obstetric cases would certainly be excessive. By careful antenatal supervision the percentage of obstetric interference in all cases in 1928 was under seven, and the forceps rate under five. Small though it was it was five-fold what obtained in the earlier period, and Mr. GIBBERD considers that this greater interference eliminated the cases of profound exhaustion in the earlier series, and with an improved technique lessened the incidence of sepsis. His comparison of the results attained in various obstetric complications is particularly instructive as showing where treatment to-day has advanced and where it has stood still. The facilities for the removal and reception of serious cases indoors must have been improved in the sixty years and also be a factor in producing better results. His paper is a valuable contribution to the maternal mortality discussion and forms a happy augury for its reduction once some such national scheme as that of the British Medical Association is put into operation. We trust that the Association will now set to work on the task of translating its scheme into legislation.

MEDICAL EDUCATION IN U.S.A.

HIGH ideals, boundless energy, and vast wealth have, in the last 20 years, completely revolutionised medical education in the United States. ABRAHAM FLEXNER'S report of 1910 crystallised the situation and was quickly followed by the extrusion of most of the incompetent and fraudulent institutions—about one-half of the whole number—and by an extraordinary increase in the equipment and efficiency of those which were left. Many of the best medical schools in the world are now in the United States. So deliberately have these changes been planned and so quickly have they been brought about that they are easily within the academic life of an individual; they can be seen from the beginning and hence form at the moment the chief object of interest for those engaged with the medical curriculum and with the methods and results of teaching. Statistical tables and graphs in the annual educational number of the *Journal of American Medical Association*, which has just reached us, illustrate the progress which is being made. It continues to be true that the number of persons who apply for admission to the medical schools is considerably in excess of the accommodation. Each good school admits a definite number of new students each year. Taking all the schools together about 60 per cent. of the applicants are accepted. In England we can, at present, only envy any school which starts with students so highly selected. The selection is continued in the subsequent years; unsatisfactory performance and laziness are rebuked once and then expelled, the loafer and the chronic are unknown. Substantial progress has also been made at the other end of the curriculum. A university degree in medicine carries with it no right to practise. For this, qualification by one of the State licensing boards is necessary. Since the Federal Government has no control over education, and since it cannot infringe any of the privileges of the State legislatures, there is no official method by which the procedures and standards of the various States can be correlated and brought into reasonable agreement with one another. But an unofficial body—"the National Board of Medical Examiners of the United States"—emanating in 1915 from Dr. W. L. RODMAN and the American Medical Association, has gone far to supply the deficiency. It holds examinations in many of the chief medical schools and grants a diploma which has so quickly established its reputation that already it is accepted by the licensing authorities of 37 States in lieu of their own examinations. It will no doubt secure the desirable end that practitioners qualified anywhere in the States can practise anywhere in the States, and not as at present only in their home State, and that the standard for qualification will be everywhere the same.

A further achievement worthy of notice is the physical realisation of an intimate coöperation between the university, the laboratory sciences, and the wards which many reformers have desired. The Rockefeller Institute has published an illustrated account of the new Vanderbilt University School of Medicine, at Nashville, Tennessee, which has been erected at a cost of something more than 1½ million pounds. In the first place, the whole school and hospital are topographically and actually part and parcel of the university; in the second place, the science departments, from anatomy and biochemistry onwards, are in the same building as the wards. The school of nursing is next door. The clinical staff includes part-time as well as whole-time teachers. It has been urged in some quarters for years past that, if the teaching of medicine is to reach a university standard, the university ought to control the wards as it does the dissecting rooms. The difficulty in doing this has been mainly financial, and the various arrangements whereby students have the run of hospitals not under university control have generally worked well enough. Recent events in Cardiff, however, have given a signal example of the dangers of the common method, and no doubt the Vanderbilt plan is preferable if someone will find the money; the cost at Nashville is about £75,000 a year for 208 beds. The housing of all departments under the same roof is certainly no less important if coöperation rather than individuality is aimed at. A common luncheon room can do a great deal to bring the laboratories and the wards together, and in the Vanderbilt school the science departments occupy the lower floors of the same blocks as carry the wards above. Theoretically, therefore, the new school seems to be a distinct advance. There is, however, at present, at any rate, one substantial criticism to make. The school admits 50 students each year and 208 beds seem quite an inadequate allowance for practical clinical teaching; there must surely be an undue proportion of theory to practice. In pathology, too, practical experience must be sadly defective. Large and important parts of pathological anatomy can be learned only in one way—on the fresh dead body. And as only about half the deaths come to autopsy, it is difficult to see how the students learn the subject which is the basis of so much of their clinical work. We should be glad to hear that the Vanderbilt school had seen the necessity and found the money to double their beds.

CREMATION AND PUBLIC SAFETY.

IT was inevitable that the series of inquests and exhumations in connexion with the late Mr. DUFF and his family should create a certain misgiving or disquietude which would find public expression. In a letter recently published in the *Times* Mr. ERNEST H. COOK, D.Sc., offers some not unreasonable comments and suggestions. He remarks in the first place that the system of disposing of the dead by cremation is one which is commending itself to an increasing number of thoughtful people on the score of communal hygiene and public health; yet, if the victims in the recent cases where foul play is suspected had been cremated, the supposed crimes would have gone entirely undetected. The files of the Director of Public Prosecutions probably contain similar instances, and it is doubtful whether the Home Office will feel disposed to view with equanimity the possibility that poisoners and others can at present escape the consequences of their misdeeds. The existing safeguards under the Cremation Rules have been regarded as adequate; there must be a sworn application from an executor or near relation who must declare that he knows no cause why cremation should not take place. There must also be two medical certificates, one from the practitioner who attended the deceased and another from a medical referee. The question is whether there should not be also a thorough post-mortem examination and chemical analysis, though, even if these additional precautions are added, mistakes may occur. Dr. Cook considers that in Mr. Duff's case, if cremation had been applied for, it would almost certainly have been granted. This, however, is by no means sure; there were puzzling symptoms about Mr. Duff's death to which his medical attendant drew attention and which removed the case from the absolutely normal; it should be possible so to frame and carry out the regulations that cremation can never be sanctioned in any case of doubt.

A second point is made by Dr. Cook with regard to judicial autopsies. No analyst, he says, can safely claim never to have made a mistake. Moreover, the analyst's task is deliberately made harder by the absence of information which might be useful to him. The coroner's officer delivers to him one or more jars containing portions of organs with the request that these shall be tested "for poisons." Our strong national desire not to prejudice a possible defendant has resulted in the practice of giving the analyst no indication of the symptoms and no aid either in ruling out one particular poison or in concentrating upon the search for traces of another. The analyst who, if fitted at all to assist in the administration of justice, would hardly allow himself to be unduly influenced by such information, is thus unfairly handicapped. Dr. Cook suggests that recourse might be had to the plan adopted in proceedings under the Food and Drugs (Adulteration) Act. In those proceedings an inspector divides the purchased article into three parts; one of these is sent to the public analyst, a second to the tradesman, and a third is retained for analysis in case of dispute. Dr. Cook holds that it is anomalous to require less careful corroboration on charges of murder than when a man is prosecuted merely for adding boric acid to milk. With his suggestions for reinforcing and confirming the evidence in murder cases and for eliminating the chance of mistake there will be general agreement. They make, however, too little allowance perhaps for the natural feelings of relatives to whom the body of the deceased is something sacred. Public opinion may tolerate interference with a dead body in the effort to detect and punish the foul crime of the poisoner; it may be reluctant to contemplate such interference as a mere preliminary to cremation in a normal case. We have given up—though not so very long ago—the barbarity of drawing and quartering the bodies of our criminals: the average citizen is probably unprepared for what (however mistakenly) he might regard as similar treatment of the bodies of the innocent.

Annotations.

"Ne quid nimis."

MASS SUGGESTION AS A CLINICAL METHOD.

Although the subject is of fundamental importance we are still far from generally accepted conceptions of the influence of mental processes upon bodily functions. In the *Münchener Medizinische Wochenschrift* of August 9th Dr. Alfred Brauchle, advocating the use of suggestion therapy by the general practitioner, offers a theory of vitalism involving the conception of an organic unconscious. This is a mind-like principle existing in hydra, the germ-cell, or man, whose action is to unify the separate bodily functions, and it is the organic unconscious that we stimulate by non-specific therapy such as the injection of foreign protein or the use of sun baths. It can be stimulated, on the other hand, by way of the mental subconscious, and Dr. Brauchle quotes several workers who have shown the influence of hypnotic suggestion in neutralising the effect of drugs upon the functions of the vegetative system. His therapy consists in elaborating to a group of patients the theory here briefly outlined and then, with the patients in a state of relaxation, using the formulæ made popular by the late Mr. Coué. He gives a table covering the results of three years' work in the Hydropathic Institute of Berlin University, and believes that his results justify the claim that the Coué method is the most useful form of psychotherapy for the general practitioner, who can by this means treat many of his patients psychotherapeutically at a cost of two or three hours a week. As a practical way of dealing with the nervous troubles that bulk so largely in ordinary practice this method has the advantage of simplicity, but its theoretical basis is questionable. Dr. Brauchle's vitalistic theory prepares the patient for the reception of the healing suggestion; its intrinsic validity seems immaterial, and any theory acceptable to the audience would probably act equally well. Essential to all such methods is the induction of belief, and, though Dr. Brauchle's enthusiastic belief in his own theory is plain, yet there are many of us who could not feel its truth even if our lives depended upon the feeling. A weightier objection to simple methods of this nature is the risk of being content with the explanation involved in them. Dr. Brauchle notes, indeed, that the mental subconscious preserves forgotten and suppressed memories, experiences, and dreams, and produces disturbers of the peace that can operate as lasting causes of illness; but he makes no further use of what modern psychopathology has taught about the intricate causes of minor mental disturbances, and leaves his readers to believe that in suggestion we have an efficient and sufficient means of handling these troubles. Suggestive treatment, based upon the most varied theories, has had its successes as far back as the history of medicine goes; it may still have a part to play but no longer occupies the whole of the psychopathological stage.

PERNICIOUS ANÆMIA.

Dr. C. Price-Jones[1] has returned to the study of the red cell diameters in anæmia and the construction of the curves which bear his name, by going back to the beginning and performing the laborious and very useful service of determining the range of normal variation by measuring 500 red cells in each of 100 healthy persons. The general average is 7·20 μ, and anything between 6·69 μ and 7·72 μ seems to be compatible with health. A few cases of frank pernicious anæmia come within these limits—5 out of 50 in the series he quotes—and he points out that a high variability of the diameters is an even more constant character of pernicious anæmia than an excessive mean diameter, though of course hæmorrhagic anæmias, in which the diameters are too small, also have a variability greater than normal. Diagnostically a high coefficient of variation with a diameter of 7·5 µ or more would put a case in the pernicious anæmia class. The effect of treatment must be gauged in the light of the range of healthy variation. He gives the data for 12 cases treated with liver extract until the anæmia was cured and the symptoms had disappeared. In nine cases the mean diameter came back within the normal range, but with one exception none became as small as the normal mean. One patient whom liver treatment restored to an active working life despite well-marked cord degeneration, still had a mean diameter as high as 7·9 µ. Similarly, some but not all of the coefficients of variation became normal. Taking one criterion with another the red cells actually became " normal " in only six of the 12 patients. This is perhaps what might be expected if liver cures symptoms without removing the cause of the disease.

MEASLES IN LONDON.

A REPORT by the school medical officer, Dr. F. N. Kay Menzies, recently issued by the Education Committee of the London County Council, gives interesting details of the behaviour of measles. Lately epidemics have occurred regularly in London at intervals of 18 months, and have lasted about six months. The disease is notifiable in two metropolitan boroughs (Paddington and Fulham), and as regards the first case in a household in seven others (Greenwich, Hampstead, Lambeth, St. Pancras, Southwark, Battersea, and Finsbury). But even if it were notifiable generally, many cases would escape notification owing to parents wrongly regarding measles as a trivial complaint.

The cases coming to the knowledge of the school authorities during the last three epidemics were: (1923–24) 41,261, (1925–26) 39,387, and (1927–28) 41,477. As measles is especially a disease of pre-school (2–5 years) age, it is estimated there were about 100,000 cases during each epidemic. The districts in which the school population were least affected were Poplar, Stepney, Bethnal Green, Southwark, Chelsea, and Westminster, owing to the fact that in the congested and poorer areas the children suffer from measles before they reach school age. The deaths during the last epidemic numbered 1357, as compared with 1034 in the previous epidemic of 1925–26. The report shows that methods of prevention, such as school closure and exclusion of susceptibles on the receipt of reports of the first cases, have failed, and that immunisation is not as yet practicable. Since 1921 a scheme has been in force, the aim of which is, by coöperation between the school and the borough authorities, to get hold of the cases early and by timely succour to prevent or secure early treatment for the complications which are the chief cause of death and permenent injury. Under this scheme efforts are made to educate the parents that measles is not a trivial disease, and to provide home nursing and removal to hospital from unsuitable homes at the earliest possible moment, and especially to concentrate efforts on overcrowded and insanitary areas, where the effects of measles are notoriously disastrous. The success of the scheme appears to depend on the closeness of coöperation between the school and the borough agencies, and it is mentioned, for example, that in Wandsworth promptitude has been secured by direct consultation between the school nurses and the borough health visitors, with an apparent effect in diminishing the mortality. Sixteen of the 28 borough medical officers of health consider the scheme valuable, and in Deptford the earlier information obtained as to cases has enabled compulsory notification to be discontinued.

The provision of hospital treatment has proved difficult. Under existing arrangements at the height of each epidemic there comes a time when selection of cases for admission must be exercised. The state of the home, and the age of the cases (measles being notoriously fatal under 2 years) are among the guiding factors. Admission to hospital after broncho-pneumonia has begun must be prompt to be of any use at all. The M.A.B. records show that during the last epidemic 8729 patients were admitted, and that of these 626, or 7 per cent., died. Of the patients admitted suffering from complications, 31·7 per cent. died, whereas of those who were free from complications on admission only 1·9 per cent. died. Broncho-pneumonia was the cause of 542 of the 626 deaths. Of the 8729 admissions, 1042 had broncho-pneumonia when admitted, and 107 more developed it within the first day. The next epidemic is due towards the end of 1929, and some of the lessons from past experience are: that more use should be made of the local knowledge of the health visitors and school nurses in order that waste of time by unnecessary visitation may be avoided, and that the needed succour may reach its objective promptly. It is also urged that the school nurses be relieved of clerical duties, such as tabulation of lists, so that they may have more time for actual visiting, and that an endeavour be made to secure even closer coöperation between school nurses and health visitors.

THE BLOOD LIPOIDS IN PSYCHOTIC PATIENTS.

A CAREFUL piece of biochemical research in which the results obtained from psychotic patients are criticised and analysed by statistical methods has recently been published by Sven Stenberg from the Psychiatric Clinic, Konradsberg Hospital, Stockholm.[1] The range of variation both in normal controls and in psychotic patients has been estimated and allowed for, and since the exact limits of the experimental error of the method used have been ascertained, the conclusions reached by the author carry conviction. In a preliminary review of the literature, Dr. Stenberg shows how little of the published work on the subject fulfils the necessary conditions, and that the variations in results are thus explained. He points out that while different methods of estimation will give discrepant results, yet each, if used alike on controls and patients, and if studied by proper statistical methods, provides material from which valid conclusions may be drawn. The method adopted by him was the micromethod of Bang as modified by G. Blix, determining the total quantity of cholesterin separately and also together with the total fatty acids. While the method has been thought unreliable by some workers, he finds that the errors are eliminated by careful technique after practice, and calculates the standard error to be negligible in comparison with the variations found in different individuals and in the same individual under different conditions. In the normal controls he finds a striking individual constancy, but a considerable range of variation between individuals, the total fatty acids, but not the cholesterin, being higher in women than in men. In the manic-depressive group of cases the total cholesterin is greater than in normal persons and also greater than during remissions. In the dementia præcox group the early cases are differentiated from those of over a year's duration; in the former the total cholesterin was found higher than in normal and remittent cases. In the latter the group taken as a whole shows no significant difference from the normal group. This result is due to the cancelling out of two subgroups; the emotionally dulled cases gave values lower than the normal, while the emotionally heightened ones were higher than the normal, an intermediate group giving approximately normal ranges of values. The general conclusion reached was that a change in cholesterin content of the blood is to be correlated with emotional disturbance, though the exact nature of this correlation has yet to be discovered. The total fatty acids give less definite results, but generally follow the same course as the cholesterin. The author suggests that the effect of insulin both on blood lipoids and on the emotional state is a line of investigation that might prove fruitful.

ARTIFICIAL LIGHT IN TUBERCULOSIS.

ARRANGEMENTS were made by the London County Council in 1926 to put into operation an experimental scheme which would enable the metropolitan borough councils to utilise the approved facilities for artificial light treatment provided at certain hospitals and centres in London. We learn from the Council's recent annual report that this experimental scheme was tried in 1927 and continued throughout the year 1928. It appears, however, from reports received from the tuberculosis officers of the 19 boroughs that little use has been made of the scheme, an average of only six cases during a period of about nine months having been recommended from each of the boroughs taking part in the scheme. The reports of these officers are said to have disclosed practically no evidence of benefit having been derived by the patients from this form of treatment. The experience of 1928 confirms the view that good results are obtained only when light treatment is given as an additional method of treatment under suitable conditions in residential institutions in the country. The London County Council has therefore decided to proceed no further with the scheme, but rather to bring to the notice of the borough councils the importance of ensuring that all cases of active tuberculosis, whether pulmonary or non-pulmonary, particularly in the early and remediable stages, should be recommended for residential treatment at the earliest possible moment.

A STATISTICAL STUDY OF HEART DISEASE IN CHILDREN.

STATISTICAL methods have not hitherto found much favour in the study of heart disease on account of the difficulty of obtaining sufficient accurate data for statistical analysis. The Heart Committee of the New York Tuberculosis and Health Association is endeavouring to overcome this difficulty by adopting a uniform nomenclature and standardising so far as possible the descriptive terms used in case-taking. The committee hopes thereby to render the observations in different clinics more strictly comparable one with another, both history and physical examination being recorded in a uniform fashion on forms which have been carefully thought out for the purpose. Their work is now beginning to bear fruit, and the third of a series of statistical studies dealing in this instance with heart disease in children has recently been published.[1] It is based on an analysis of the case-histories of 500 children observed in a clinic under the same medical supervision during a period of ten years, 38 per cent. of the cases having been kept continuously under observation for more than three years.

In this series 50 per cent. of the children were between the ages of 6 and 10 at the time they were first seen, and 62 per cent. were over 11 years of age at the end of the period under review. Seventy-nine per cent. of the whole series gave a rheumatic history and of these three-quarters developed organic heart disease, the remainder being provisionally classified as "potential cardiacs." In the affected cases the heart lesion generally became manifest within 12 months of the onset of the rheumatic infection, and in point of fact was probably synchronous with it. In 50 per cent. of the rheumatic cases in this series the first infection occurred between the ages of 6 and 9, the average age of onset being 7·3 years. It appears that about the age of 12 a certain degree of immunity begins to develop, older children being less liable to infection, and the writers point out the importance of bearing this fact in mind when attempting to evaluate the results of therapeutic measures. Relapses occurred in 73 per cent. of the cases studied, and were most common within three years of infection. This figure, however, is probably an underestimate of the true incidence of relapses, for many of the cases in which no relapse was noted were under observation for only a short period of time. In the age-groups between 3 and 9, comprising 234 cases, the first relapse took place within one year of the onset in about 50 per cent. of cases, while in the smaller group where the first attack occurred after the ninth year, the percentage of cases in which the first relapse occurred within 12 months was 72 per cent. The writers suggest that the onset of puberty may possibly be a factor in predisposing to early relapse in these cases. Twelve per cent. of the children died, the most common age of death being between the eleventh and fourteenth years; 88 per cent. of the deaths were attributed to rheumatic heart disease. The writers are strongly of opinion that "growing pains" are of no less significance than chorea or polyarthritis as a manifestation of rheumatic infection, but they do not consider that any of the extracardiac manifestations of rheumatism can be regarded as giving an indication of the degree of heart involvement. Rheumatic nodules occurred in 60 patients, appearing most frequently at the end of periods of acute infection; 20 of these children died. With regard to valvular lesions, it is interesting to note that of 157 children, who appeared to have only mitral regurgitation on admission, 48 eventually developed stenosis; in 34 of these the stenosis took three years or more to develop.

The crippled hearts which result from rheumatic infection in childhood constitute one of the most tragic pictures in the wards of our great hospitals. Their future seems so hopeless, and it is encouraging to learn from the American analysis that so far as the functional results are concerned the outlook is on the whole quite good, for in 70 per cent. of the present series there was little or no impairment of the exercise tolerance. This justifies the belief that although we are still far from being able to prevent rheumatic infection, we can at least hope to limit its most serious sequelæ. The object of the New York Committee is to collect a sufficiently large mass of information concerning heart disease in order to be able to treat it statistically. There are bound to be differences of opinion as to the value of the results so obtained; but provided the data are reliable and sufficient care is taken to limit the inquiry to simple issues, from which complicating factors can be definitely excluded, information of real value will be obtained. While it may not be right to speak of definite "laws" in biology in the sense in which the word is used in physics or chemistry, we may at any rate hope by work of this kind to ascertain the general tendency of rheumatic disease and the extent of variation in individual cases.

FAT AS AN ESSENTIAL ARTICLE OF DIET.

SINCE the discovery of the fat-soluble vitamins there has been a tendency to regard fat as being an unimportant dietary constituent, capable of substitution by carbohydrate, when once those vitamins of which fats are the ordinary vehicle have been adequately supplied from some other source. J. C. Drummond[1] in 1921 reared and bred young rats on a fat-free diet, supplying the fat-soluble vitamins as the unsaponifiable fraction of cod-liver oil. The subject has been attacked again recently by G. O. Burr in conjunction with H. M. Evans[2] (1928) and with M. M. Burr[3] (1929); in their experiments the growth of rats was checked and lesions developed when fat was completely excluded from the diet. Growth was promoted and the lesions were prevented or cured by the addition daily of 10 drops of lard or other fat, or of the fatty acids from lard, but not by the addition of glycerol or of the unsaponifiable fraction from lard. The Burrs go so far as to describe the condition produced as "a new deficiency disease produced by the rigid exclusion of fat from the diet." The symptoms described, of which an annulated and necrotic condition of the tail is particularly characteristic, are not unlike those which occur in pellagra of the rat, caused by an insufficiency of vitamin B 2, but the Burrs are emphatic that increase of the supply of the B-vitamins by means of ether-extracted yeast had no effect upon the syndrome. They do not, however, make it clear that ether extraction might cause yeast to be deficient in vitamin B 2. H. M. Evans and S. Lepkowsky[4] (1929) have come to the conclusion that the inclusion of large amounts of fat in the diet of rats has a very important effect upon the body's requirements of vitamin B 1. They describe the phenomenon as "the sparing action of fat on the antineuritic vitamin B" and show that even when there is no vitamin B 1 in the diet, vitamin B 2 being provided in the form of autoclaved yeast, the rat can survive if the diet contains as much as 50 per cent. of fat; if small but still insufficient amounts of vitamin B 1 are given to the rat, the amount of fat which will produce normal growth is less than 50 per cent. The "sparing" action is considered by Evans and Lepkowsky to apply only to vitamin B 1, for when the latter was given, as an alcoholic extract of rice bran, and vitamin B 2 was withheld, the weight curves of the rats are interpreted as showing that the addition of fat had little beneficial effect. In our view the weight curves do not quite bear out the interpretation that the saving action of fat applies only to vitamin B 1, for there is a very marked improvement in them when fat is added to the diet deficient in vitamin B 2. There is thus in both these sets of observations certain common ground for suspecting that the B-vitamins are involved in explaining the part played by the fat. Inclusion of fat in the diet might operate on the organism in many other ways than straightforwardly as a correction of a simple deficiency of fatty acids. The biological study of the B-vitamins is set about with the most thorny difficulties, such as are introduced by the habit of coprophagy and the phenomenon of refection, and it is perhaps rather hasty to interpret these observations on rats as evidence of a new deficiency disease.

PAROXYSMAL SNEEZING.

THE average text-book of medicine has little to say about sneezing, beyond the vague statement that a sneeze is an involuntary reflex respiratory act. Yet the sneeze is a symptom of many disorders from hay-fever to the common cold; it may be the first sign of measles or only the result of stimulation of the optic nerve by a bright light. The Greeks and Romans considered the sneeze as a definite omen from the gods and it was one of the common everyday phenomena, which if it occurred at a moment of special import could be interpreted as presaging the future. There are many allusions to sneezing in classical literature, but it is a line from a popular refrain well known to a former generation "He sneezed so hard with the whooping-cough" which is most relevant to the case recently described by Dr. Alan Moncrieff and Dr. R. C. Lightwood.[5] A little girl began an attack of whooping-cough in the ordinary way at the end of January, 1929. At the beginning of March she ceased to whoop and began to sneeze instead. Her sneezing attacks occurred about ten times a day and each attack caused great distress and incontinence of urine. She had suffered from these attacks for three weeks when she developed the broncho-pneumonia which led to her admission into hospital. There the paroxysms of sneezing continued, although she did not cough or whoop. The paroxysm consisted of a rapid series of "expiratory sneezes" resulting in the expulsion through the nose of large quantities of tenacious muco-pus. At the end of the paroxysm the patient drew in her breath and lay back cyanosed and exhausted. As the broncho-pneumonia got better a slight whoop developed and for a time she had both whooping and sneezing attacks. At the end of six weeks from the onset of the pneumonia the whoop had disappeared, although occasional mild sneezing attacks continued. Bacteriological examination of the muco-pus discharged from the nose in one of the paroxysms demonstrated the presence of Gram-negative bacilli of the pertussis type. This variation in the normal course of whooping-cough was apparently well known to the physicians of many years ago, for there is an allusion to it in an interesting treatise on the disease by Dr. Thomas Watt, of Glasgow, published in 1813. Several continental authors refer to the condition which has also been described by J. P. C. Griffiths and A. G. Mitchell, and by J. D. Rolleston. Szegö, of Budapest, suggested in 1900 that such sneezing attacks made it probable that the spasmodic features of pertussis had a central origin. More recent writers have mentioned other equivalents of the whoop in pertussis and the list includes paroxysmal hiccough and paroxysmal yawning. Dr. Moncrieff and Dr. Lightwood give a short review of the literature of the subject and note that adults with apparently intractable coryza may really be suffering from whooping-cough and may infect children. Apart from their rare appearance in whooping-cough, true paroxysms of sneezing are mainly associated with anaphylactic disorders such as hay-fever; when they develop suddenly in children not sensitive to pollen, the possibility of whooping-cough should be considered.

STERILISATION OF THE UNFIT.

WHILE those most intimately concerned with the care of the mentally defective in this country continue steadily to oppose sterilisation as an auxiliary measure to the more important segregation, a number of interested people continue to press its claims. They are encouraged by the results of American experiments, which have caused the majority of social workers and medical men concerned with the problem of amentia in the United States to advocate a carefully safeguarded authority for sterilising suitable cases. Dr. K. B. Aikman returns to the subject in the *Edinburgh Review* for July. He begins by attacking the doctrine of the equality of man, and goes on to deplore the racial suicide of the middle classes. He does not believe that the peculiar qualities of these classes can be perpetuated for the nation by constant recruitment from lower strata. He attributes the "suicide" to a complex of many factors: increasing density of population with increasing competition, calling for longer training for learned professions and technical occupations, and hence later marriages and a greater cost of launching children into the world, while the earning power of the manual labourer is at its highest when his physical growth is complete. A higher standard of living, a reduced value of money, and an increasingly materialistic outlook have led to the reduction of families, which has been facilitated by modern methods of birth control. Coincidently with this decrease in the middle-class population there has been an actual increase in that of the poorer classes, for every new triumph of hygiene has produced its first results among the poor. The decrease in the infant mortality-rate is a reflection of the number of lives saved to the working-class population, and Dr. Aikman would temper our self-congratulation on this achievement because it is based on statistics which pay no heed to quality. He finds cause for anxiety in all directions: the recruiting figures of 1917–18, the lack of fit emigrants, the ill-health of school-children, and the amount of time lost through sickness among the insured population. He finds the increase in the number of insane and mentally defective persons most disquieting. The difficulties in the way of remedy appear to him to be purely ethical; we are not able to increase the death-rate by failing to encourage the survival of the less fit, and all we can do is to fail to encourage the arrival of the less fit. He claims that measures designed primarily to increase the number of better citizens should be directed broadly to the assistance of those sections of the community which contain the greatest proportion of desirable characteristics. Since persons handicapped by disease and antisocial qualities will always tend to gravitate to the worst paid employments and most slovenly surroundings, the poorest classes must always contain a large proportion of the least desirable citizens. In view of this fact, and of the fact that the main bulk of the people lie close to the average of any given quality, and that it is impracticable for everybody to have as many children as is physically possible, a slight increase in fertility of the fairly large numbers who are just above the mean and a slight decrease in the equally large population which is just below the mean will do more for the race than trebling a few highly superior families. The legislation at which Dr. Aikman would aim must accord with the dictates of humanity, must increase the fertility of the middle classes, and must avoid the selection of individual beneficiaries by bureaucrats. Numerous economic measures have been tried or suggested; all of them are capable both of good and of harm and all have proved disappointing in practice. Economic measures alone cannot solve the problem. The solution must depend on the recognition of responsibility. In this country we have no law requiring that persons discharged from mental institutions should even be warned that their weakness may be transmissible, and indeed it is common enough for defective girls to be discharged by magistrates on condition that they marry. The only way out of our parlous situation seems to Dr. Aikman to be the sterilisation of persons who are well enough to be discharged from mental institutions but who are certain or highly likely to produce defective offspring. He grants that segregation is an ideal measure, but regards it as wholly impracticable if only on the ground of expense. He considers that legislation to check procreation by the unfit should have an educational influence on the general public out of all proportion to the number of individuals actually affected. In answer to the criticism that this interferes with the liberty of the subject, he points out that this question must be considered from the point of view of the greatest happiness of the greatest number, and, in Dean Inge's words, "by far the greatest number are not yet in existence."

BENEFACTORS OF MANKIND.

THE *Manchester Guardian* has recently held a competition to choose six persons who might lay claim to the distinction of being called the greatest benefactors of mankind, Lister being the type suggested, and therefore excluded from the list. The six representing the votes polled were:—

1. Pasteur.
2. J. Y. Simpson.
3. Mme. Curie.
4. Rontgen.
5. Jenner.
6. Ross.

The readers of the *Manchester Guardian* are well known to be the most intelligent group of citizens in this country, and it is gratifying to find that they set such a high value on the relief of pain and suffering. It is also interesting to note that they put this particular interpretation on "benefactor," though this may be due to the suggestion made in the setting of the competition that Lister was a good example. On this view a "benefactor" is one who makes life more tolerable. The concise Oxford Dictionary says "person who has given one friendly aid," which is compatible with the view that the best benefactors of mankind are those who have enlarged human life, more especially in the intellectual and spiritual spheres. Of the chosen six, Curie alone would satisfy this criterion, and she comes third, probably because radium is good for cancer, and not because its discovery is one of the great events in our understanding of the natural world. Darwin would come here too, though he was suggested by only a few of those who sent in lists. The problem set is, of course, insoluble, as most interesting problems are. But whatever the answer which is most nearly right, it is encouraging to see medicine so highly thought of.

INTERNATIONAL SOCIETY OF MEDICAL HYDROLOGY.

THE sixth annual meeting of the Society will take place at Budapest from Oct. 13th–18th, under the patronage of the Archduke Dr. François Joseph and members of the Government. Medical discussions on the 14th and 15th will deal with the Action of Hypertonic Waters and the Use of Baths and Waters in Cardiovascular Affections. A meeting of the Ligue Internationale contre le Rhumatisme will be held on the 16th to consider the Relation between Acute and Chronic Rhumatism in the Various Countries and the Hæmatology and Serology of Rheumatism. The Society will be entertained by the Prime Minister, the City of Budapest, and by the Balneological Society of Hungary. Excursions will be made to the "Bitter Water" springs, the bathing establishments, Lake Balaton, and other places of interest. At the conclusion of the meeting the party are invited to visit Vienna to view the hospitals and clinics and the establishments at Baden. Special reductions in cost are offered to the Society and their friends. The English party will leave London on Friday, Oct. 11th, and a few vacancies are available for medical men or women who are interested in hydrology. Particulars on application to the Hon. Secretary of the Society, 130, Marylebone-road, London, N.W.1.

FACIAL ERYSIPELAS.

IN a contribution to the *Jour. Amer. Med. Assoc.* of August 10th Dr. David Seegal and Dr. Beatrice Seegal have analysed a series of 281 cases of facial erysipelas admitted to the wards of the Massachusetts General Hospital between the years 1870 and 1927 into nine somewhat arbitrary categories. Their results are illustrated by graphs of value to the statistician or to an epidemiologist, if of little interest to the practitioner. In their summary of conclusions the following points are worthy of note. The months of greatest frequency were from May to December, when, though this may be a coincidence, sore-throats due to the *Streptococcus hæmolyticus* are most frequent. Thirty-eight of the cases (13·5 per cent.) occurred in the hospital personnel; of these, 22 were nurses, 12 were members of the domestic staff, 3 were laundry workers, and 1 was a physician. The inference seems to be that these cases were the result of actual contact, direct or indirect. Forty-eight per cent. of the 281 cases occurred in patients after admission to hospital; about half this number were medical patients, the rest surgical, in whom slightly more than half had recently undergone some facial operation. The temperature was usually high during the first two days of the disease, and in about three-quarters of the total number of cases reached 104°–105° F. at some period of the evolution of the attack. The untreated case left to its natural course sometimes terminates abruptly by crisis in from 4–7 days. The mortality in the series was 10·6 per cent. This figure includes patients who were suffering from some other serious disease at the same time. When these are excluded the percentage of deaths works out at only 5. As is generally known, the prognosis is most serious at the two extremes of life.

This analysis, extending over 60 years, is interesting, but it is doubtful if the conclusions reached are of much practical importance at the present time. All modern observers will agree that true fulminating and terminal cases, such as were doubtless common before the days of antisepsis, are exceedingly rare in our day. Whether this is due to the diminished virulence of streptococci, to which the mildness of present-day scarlet fever is attributed by some epidemiologists, is of theoretical interest. It is significant, however, that the dermatologist sees a considerable number of mild cases of a relapsing type, and it would be worth while to ascertain if these, when added to the number of cases falling into the true acute group, would bring the total number of cases of erysipelas occurring in the periods 1875–1885 and 1919–1929, in a given hospital, to approximately the same total figure. Protein shock treatment has given a very much better outlook to all cases of erysipelas. Experience seems to indicate that a specific serum is not more potent than any foreign protein capable of producing the chain of phenomena we term shock, and that it is therefore unnecessary to jeopardise convalescence by injecting horse serum when milk protein will have the same therapeutic effect. In cases of the subacute relapsing type on the face, if the focus of the infection is not discovered and treated, continual recurrences with ultimate local complications, such as lymphangitis and a form of intractable elephantiasis, are to be feared. Unfortunately, the utmost diligence and patience sometimes fail to reveal a focus, and it is in these cases that the prognosis as regards complete restoration is unsatisfactory.

SEXUAL REFORM CONGRESS.

THE Third International Congress of the World League for Sexual Reform, which is being held at the Wigmore Hall, London, during the present week, opened on Sunday evening in the presence of about 120 members with an address of welcome from one of the Presidents, Dr. Magnus Hirschfeld, of Berlin, the hon. treasurer, Mrs. Dora Russell, and the hon. secretary, Dr. Norman Haire. Dr. Hirschfeld recalled the last occasion when he spoke in London, at the International Medical Congress of 1913, when the meeting was interrupted by suffragettes. Much of the progress for sexual reform since made he attributed to the political emancipation of women which had taken place in this and other countries. It was, he said, only during the present century that sexual science was winning for itself an independent position among the natural sciences. Sexual biology was still in its infancy, and much of what had been written on the subject had been dictated by points of view other than purely scientific. Sex abnormality was, he said, a fact which must be reckoned with, and should neither be over- nor under-estimated. One point he wished himself to emphasise at the outset of the Congress was that men and women whose sexual temperament diverged from the normal should neither marry nor have children. Mrs. Russell also recognised the fruitful effect of woman's political emancipation on her economic and sexual equality. Scientific investigation of sex problems would not in itself affect conduct, but was a necessary preliminary to other measures. While she hoped that a congress in London would bring publicity to the movement, she felt that its most substantial advantage would result from the free discussion between men and women of subjects which concerned them both equally. Dr. Haire set out briefly the objects of the League, the first of which is *a political, economic, and* sexual equality of men and women, which included the liberation of marriage and especially divorce from the present tyranny of Church and State, the control of conception so that procreation may be undertaken only with a due sense of responsibility, and a rational attitude towards sexually abnormal persons. Many of the aims are common to other spheres of social activity, but it is a thesis of the League that only those sexual acts should be considered criminal which infringe the sexual rights of another person. In the programme of the Congress, which is a very full one, a whole day is allotted to the vexed question of sex and censorship, to which a number of distinguished literary men are contributing.

THE EFFICIENCY OF CARDIAC MASSAGE.

THE observations of the coroner in a recent case in which heart massage restored the circulation after failure during anæsthesia raise the important question of the time at which this extreme measure should be employed. The fact that effective cardiac massage cannot be applied to the adult without opening the abdomen makes it obviously desirable to employ this form of resuscitation only as a last resort unless the abdomen has already been opened during the operation. At the same time if it is to be used with any benefit certain time limits must not be overstepped. It is generally held that artificial respiration should have been efficiently employed for fully five minutes before cardiac massage is attempted. There are now quite a large number of cases on record in which restoration of the circulation was attributed either to cardiac massage or to intracardiac injection of adrenalin. It is not certain in all these recorded cases that properly carried out artificial respiration would not have been successful, even without direct stimulation of the heart muscle. The ultimate prognosis in these patients depends on the power of recovery of the brain cells, which are those most readily damaged by stoppage of the circulation. It is generally held that the cortical cells cannot be revived after about 15 minutes of circulatory deprivation. Dr. T. Lumsden notes (see p. 585) that in his experiments on cats the cerebrum never revived if the circulation had entirely ceased for five minutes. In the well-known case at Guy's, in which a child ultimately recovered after weeks of illness indicating the cerebral damage that had been sustained, it was reckoned on good evidence that 13 minutes elapsed between the collapse during anæsthesia and the moment when cardiac massage restored the circulation. Prof. J. A. Gunn, whose investigations into the condition of arrested circulation have been valuable, recommends that in performing cardiac massage the compression should be gradual and the relaxation abrupt, that the rate should be less than half the normal heart-rate, and that there should be interruptions at short intervals to allow spontaneous beats to develop. Prof. Gunn also recommends an intravenous injection of atropine after the heart has restarted as the best means of averting secondary stoppage from excessive vagal action which has been responsible for death *after* the primary circulatory failure has been corrected.

WE regret to announce the death of Mr. Charles Alexander Morton, emeritus professor of surgery in Bristol University and consulting surgeon to the Bristol General Hospital. His death occurred on Sept. 7th in Switzerland, where he was on holiday.

CHARTERED SOCIETY OF MASSAGE AND MEDICAL GYMNASTICS.—The Members' Congress will be held in London on Oct. 15th to 19th, all the lectures except the lantern lectures being given in the Great Hall of the B.M.A. House, Tavistock-square. Sir Henry Gauvain will give the first lantern lecture on The Treatment of Tuberculous Cripples: Sun and Sea Bathing, at 11 A.M. on Oct. 15th, at the Central Hall, Westminster, and the other lectures to be given at this hall include one by Mr. Naughton Dunn on Principles in the Treatment of Common Deformities at the same time on Oct. 17th, and one by Dr. A. F. Hurst on Asthma at 6.30 P.M. on Oct. 17th. Other lectures will be by Mr. H. Chapple on Twilight Sleep, Dr. Cicely M. Peake on Rheumatism in Children, Dr. Justina Wilson on Diathermy, Mr. P. Jenner Verrall on Low Backache, and Dr. G. J. Langley on Cardiac Insufficiency. Sir Cooper Perry will preside at the annual general meeting on the 19th, and the first annual dinner of the Society is to be held at the Café Royal, Regent-street, on Wednesday, Oct. 16th, at 7.45 P.M.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

XLIII.—SIGNIFICANCE OF THE ACID-BASE BALANCE IN THE BLOOD.

PART II.*—DIAGNOSIS OF ACIDOSIS, ALKALOSIS, AND KETOSIS.

Acidosis.

WE have agreed to use the term acidosis for a condition in which the bicarbonate concentration of the body fluids is reduced by retention of acid or loss of base. The obvious method of detecting such a condition is to measure the plasma or blood bicarbonate. We have, however, to remember that the plasma or blood bicarbonate may be reduced in order to raise the cH towards normal when the free carbonic acid concentration has been reduced by overbreathing (type 1 (*b*)). In many cases there is no doubt as to which condition is present—for example, in diabetic ketosis in which we know that an excess of acids is being formed—but in other cases the answer is not obvious. For example, a moderate reduction of plasma bicarbonate, down to about 45 is found in anæsthesia; abnormal acid formation or retention sufficient to account for such a reduction has not been demonstrated, and it was at one time widely maintained that this reduction was the result of compensation for hyperpnœa. However, in these cases the range of pH is found to be below normal—that is, cH is above normal—which leaves no doubt that the reduction of c(NaHCO$_3$) is primary. In cases of doubt, therefore, it is necessary to measure the pH of the blood as well as the bicarbonate.

Measurements of plasma or blood bicarbonate present several difficulties owing to changes in the blood on exposure to air or on standing, and it is advisable that the sample of blood should be taken by someone familiar with the technique; still greater precautions are required even for rough pH measurements.

As shown in Table II. last week there is always some compensatory reduction of free H$_2$CO$_3$ in acidosis, although the attempts at compensation may fail to bring the pH back to normal. If there is no interference with the respiratory exchange the alveolar air is in equilibrium with the plasma, so that the CO$_2$ tension in the alveolar air is proportional to the amount of CO$_2$ dissolved as H$_2$CO$_3$. Consequently the CO$_2$ tension in the alveolar air is reduced in acidosis; but, since the CO$_2$ tension is only reduced proportionally to the bicarbonate when the acidosis is fully compensated, it does not give such a good measure of the degree of acid retention as does the plasma bicarbonate. Also the patient's coöperation is needed in obtaining samples of alveolar air, which may be an insuperable objection. For these reasons estimation of the plasma bicarbonate is usually preferred. As set out in Table II. the amount of CO$_2$ per 100 c.cm. of normal plasma is 55 to 65 c.cm., while in conditions of acidosis it varies from 14 to 45.

Sellard's Test.—After taking 5 grammes of NaHCO$_3$ by the mouth a normal person usually excretes alkaline urine; but in acidosis the urine remains strongly acid (acid to methyl red) until enough NaHCO$_3$ has been taken to bring the plasma bicarbonate up to normal, which may require some 60 grammes. This gives a method of measuring the degree of an acidosis (Sellard's test) which is, however, rarely used.

Acidosis may be produced by any acid that is not poisonous in small concentration; the type most commonly seen among hospital patients is that due to retention of phosphoric and sulphuric acid in severe renal impairment. Such an acidosis usually occurs in cases of chronic nephritis with nitrogen retention as they approach the common end of all cases of this type, and may reach a severe degree as shown in Table II. of Paper I. The lowest pH recorded in man, 6·7, was found shortly before death in a patient with nephritis.

Alkalosis.

Failure of compensation, with consequent rise of pH, is usual in alkalosis, and the symptoms then are similar to those that occur in voluntary hyperpnœa and at high altitudes before accommodation is gained. Headache, dizziness, disturbed sleep, and a sense of weakness occur with the slighter degrees of elevation of pH; with more advanced degree, drowsiness, coma, tetany, and even general convulsions.

Alkalosis does not, like acidosis, occur in normal persons, and does not occur so often as a result of disease. It is caused by loss of hydrochloric acid in vomiting, particularly in the profuse vomiting that occurs with high intestinal obstruction or dilatation of the stomach due to other causes, and probably contributes to the extreme collapse in these conditions. On the other hand, alkalosis is more likely than acidosis to result from therapeutic measures, since the local effects of acids discourage their administration in large doses, the potential acids ammonium chloride and calcium chloride are unpleasant to take, while sodium bicarbonate which appears innocuous may be given in large quantities. When alkalis are given as a treatment for acidosis they should be stopped when the urine ceases to be strongly acid; it is best to use the indicator methyl red, which gives a red colour with a strongly acid urine (pH under 5·5).

Alkalosis can be detected and measured only by estimation of the plasma or blood bicarbonate, preferably with estimation of the pH as well. The CO$_2$ may rise to well over 100 c.cm. per 100 c.cm. of plasma. When large doses of alkalis are given, for example, in the treatment of pyloric ulcer, it is advisable to check the effect by plasma bicarbonate estimations; should this not be possible, it is necessary to watch for the symptoms of alkalosis—headache, nausea, weakness, and drowsiness.

The condition *alkalæmia*, an increase of the pH of the blood, can only be diagnosed with certainty by an actual estimation of the blood pH. So-called

* Part I. appeared last week.

renal asthma is a condition of this type; the hyperpnœa is not brought on by acidosis but by an interference with the blood-supply to the respiratory centre, and occurs particularly in hyperpiesia.

Ketosis.

Ketosis, the appearance of acetone bodies in the urine, occurs particularly when the ratio of carbohydrate metabolised to fat metabolised is low; as in diabetes mellitus, starvation, and when the proportion of carbohydrate to fat in the diet is much reduced. It also occurs in fevers, especially in children, and to moderate degree in various other conditions, not uncommonly in normal pregnancy, and frequently in alkalæmia. It is undesirable that the term acidosis should be used for the appearance of acetone bodies in the urine, since this appearance need not be accompanied by any reduction of plasma or blood bicarbonate, and excessive formation or retention of acids may occur quite independently of the acetone bodies; also acetone bodies may appear in the urine in a patient with alkalosis. This is not merely a matter of nomenclature; Prof. A. E. Ellis has recorded the case of a drowsy patient in whose urine acetone bodies were found; the diagnosis of acidosis was made, and she was given sodium bicarbonate; as the ketosis became worse and the patient more drowsy, the sodium bicarbonate was repeated in heroic doses until she became comatose, developed tetany, and died. Shortly before death her plasma bicarbonate was found to be very high. It is very probable that this patient was suffering from alkalosis from the beginning.

Rothera's Reaction.

Ketosis is usually diagnosed by the detection of acetone and aceto-acetic acid in the urine. It is unfortunate that there is no qualitative test for β-hydroxybutyric acid, which is excreted in larger quantities than acetone and aceto-acetic acid in the more severe degrees of ketosis. The test that should invariably be used is Rothera's nitroprusside reaction, which is given by both acetone and aceto-acetic acid. The ferric chloride reaction which is given by aceto-acetic acid is also given by many other substances, particularly salicylic acid and its derivatives, such as aspirin. When present in small quantities the colours given by these substances are indistinguishable from that given by acetoa-cetic acid, and the methods for differentiating them are unsatisfactory. It is therefore advisable not to use the ferric chloride test unless the nitroprusside reaction is positive, and then to draw no conclusions if there is any likelihood that the patient has taken any such compound as aspirin.

In order to estimate the severity of a ketosis we may first estimate the amount of acetone bodies excreted in the urine. The straightforward estimation of the total acetone bodies is a long process not suitable for daily repetition. The depth of colour of the nitroprusside reaction gives some indication; if the colour is only pink the degree of ketosis is slight. The most popular index is the strength of the ferric chloride reaction. As might be expected the results are not very satisfactory, since the substance measured by this reaction is not the principal one excreted when the ketosis is severe. A definite reaction indicates that a large amount of acetone bodies (over 6 g. in 24 hours) is being excreted and a strong reaction that the amount is excessive; but a large amount may be excreted with no ferric chloride reaction.

An indirect estimate of the amount of acetone bodies in the urine can be obtained from the amount of ammonia in the urine, which is increased when the total amount of any acids excreted is increased; the parallelism between ammonia and acetone body excretion is particularly good. It is, of course, essential that the patient should not be receiving alkalis at the time, and that the urine should be collected with some preservative such as toluol, to prevent the formation of ammonia from urea by bacteria.

When substantially the whole of the 24 hours' urine cannot be collected, it is not possible to draw any conclusion from the ammonia concentration; some help may be given by the ratio of ammonia nitrogen to urea nitrogen; this ratio is normally about 1/30, and rises as the acid excretion rises; but it must not be forgotten that this ratio also falls when the protein intake is reduced, and no conclusions should be drawn unless the ratio is about 1/10; in extreme cases it may rise to unity.

Table III. gives examples of various degrees of ketosis. The amount of acetone bodies retained in the body fluids is of more importance than the amount that is being excreted harmlessly in the urine. A moderate amount may be excreted without any appreciable retention, and patients vary greatly in the relation between amounts excreted and amounts retained. The straightforward estimation of acetone bodies in blood is too long for repeated use. If the patient is not taking alkalis the plasma bicarbonate will give an indication of the degree of retention and has been largely used; but the bicarbonate reduction is not necessarily proportionate to the amount of acetone bodies, as other acids besides β-hydroxybutyric and aceto-acetic may be formed.

As a rough quantitative measure the nitroprusside reaction may be applied to the filtrate obtained in the *Folin-Wu method of sugar estimation*; a pink colour developing in about 15 minutes shows an excess of acetone bodies. This test might well be used more generally.

JOHN R. MARRACK, D.S.O., M.D. Camb.,
Chemical Pathologist to the London Hospital.

DONATIONS AND BEQUESTS.—Mr. Mark Firth, of Carlton-park, Northampton, left £1000 to Firth's Almshouses, Sheffield, and £100 each to the Royal Infirmary, Sheffield, the Royal Hospital, Sheffield, the Jessop Hospital for Women, Sheffield, the Free Hospital for Sick Children, Sheffield, and the Kettering Hospital, —The late Miss Marianne Hamilton, of Maclog Cottage, Beaumaris, Anglesey, left, among other bequests, £1200 to the Royal Alexandra Convalescent Home, Rhyl; £1000 each to the Anglesey and Carnarvonshire Infirmary, the Society for the Prevention of Cruelty to Animals, Dr. Barnardo's Homes, the Mission to Lepers, the Church of England Zenana Missionary Society, the Oldham Deaf and Dumb Institution, and the Oldham Home Teaching for the Blind; and £500 to the Beaumaris and District Nursing Association. The residue will be divided between the Royal United Kingdom Beneficent Society, the Oldham Royal Infirmary, Henshaw's Bluecoat School, Oldham, and the Northern Hospital for Incurables, Mauldeth, Manchester.—Mr. Charles Wellington Polkinghorne, of The Terrace, The Hoe, Plymouth, left £500 each to the South Devon and East Cornwall Hospital and the Royal Albert Hospital.—The Governors of the Manchester Royal Infirmary have received a legacy of £5898 from the late Mrs. M. A. Gratrix, and one of £1000 from the late Mr. Edwin Ogden.—On the decease of a legatee, Mr. William Malin, J.P., of Overdale, Derby, left £600 to the Derbyshire Royal Infirmary for the endowment of a cot in memory of his son. Mrs. Virginia Schilizzi, of Paris and of Athens, and Highgate, London, left £1000 to King Edward's Hospital Fund for London, and £500 each to Westminster Hospital and the Grosvenor Hospital for Women and Children, Vincent-square, London, S.W.—Mr. George Brookfield, of Queen's Drive, Mossley Hill, Liverpool, left £500 each to the Child Welfare Association, Liverpool Hospital for Diseases of the Heart, Liverpool Children's Hospital, and the Boys' Home and Refuge, Liverpool. One-half of his residuary estate is to be divided between the Liverpool Royal Infirmary, the Liverpool Hahnemann Hospital, the George Walker Memorial Hospital, and the Liverpool Central Relief Society.—Mr. Frank Walker, of Normanton-road, Derby, left £500 each to the Derbyshire Royal Infirmary, the Derby and Derbyshire Hospital for Sick Children, and the British Empire Cancer Research Society.—Mr. Thomas Lewis, of Haslingden-drive, Bradford, left £150 to the Leeds General Infirmary "as a grateful appreciation of the successful serious operation performed upon me by Dr. Littlewood at the infirmary" and £150 to the Bradford Royal Infirmary.—Mr. Joseph Cottrell, of Rugeley, Staffs, left, on the death of his wife, £1000 to the Derbyshire Royal Infirmary for the endowment of two beds in his name and £1000 to the Stafford General Infirmary for the endowment of two beds in his name.

Special Articles.

ON THE VALUE OF TONSILLECTOMY

IN THE PREVENTION OF ACUTE RHEUMATISM, RHEUMATIC CARDITIS, AND CHOREA.

BY N. GRAY HILL, *M.C.*, M.B. LOND., D.P.H.,
ASSISTANT MEDICAL OFFICER, QUEEN MARY'S HOSPITAL, CARSHALTON, SURREY.

IT is very widely held that the tonsils are the portal of entry of the hypothetical causal organism of rheumatic fever, and Poynton's declaration "I am convinced by clinical and experimental evidence that the tonsils are the site of access; statistics will not shake me in this belief," clearly defines the attitude of a number of medical men who have had wide experience of the rheumatic disease. Further, it is commonly claimed that the tonsils of rheumatic children are unhealthy and show evidence of chronic or subacute inflammation.

The theory that the infection enters by the tonsils is difficult either to prove or disprove. Until a definite organism can be incriminated, satisfactory experimental evidence cannot be obtained, and it must be remembered that although a fairly strong case has been made out by certain investigators against various streptococci, no organism is as yet generally accepted by the bacteriologists as the specific organism. The statement that the tonsils of rheumatic children are in a worse condition that those of their healthy brethren may be true, but unhealthy children tend to have unhealthy tonsils and a fundamental relationship between the tonsil and the disease from which the child suffers is not thereby proved. At the Bath Conference on Rheumatism Wilfred Vining stated that in his experience tonsillitis and sore-throats are as commonly met with among non-rheumatic as among rheumatic patients, and MacSweeney published figures, collected while examining school-children in Cardiff, that suggest that the alleged association between enlarged and septic tonsils and acute rheumatism does not exist. Boas and Schwartz, in a paper on the modes of infection in rheumatic fever, regard the tonsils as playing a relatively minor rôle as a source of infection, and other workers, both in this country and in America, have shown that there is not such a marked difference between the tonsils of rheumatic children and others as to warrant the dogmatic statement that the tonsils of rheumatic children are hypertrophied and either acutely or chronically inflamed.

Some Published Investigations.

But even if the tonsils were the common portal of entry it is questionable if the permanent closure of a gate after an enemy has entered will save the city. Schichhold, in a paper published in Munich in 1910, claimed that the removal of the tonsils would cure an attack of rheumatic fever and prevent recurrences, and this hypothesis has been accepted by many. Robey and Freedman endorsed it. They concluded from their investigation of 454 cases that complete enucleation is the best preventive treatment for rheumatic fever and endocarditis, and considered that tonsillectomy should be performed when there is a history of sore-throats, even when the tonsils appear normal, and when the tonsils appear diseased, even though sore-throats are absent. They refer to the beneficial results they obtained by tonsillectomy conducted during the height of an attack of acute rheumatism. Kerley, writing in February, 1929, asserts that the tonsils should be immediately removed from a patient suspected of having rheumatism, regardless of whether they appear healthy or not. Reginald Miller is of opinion that tonsillectomy is of great value in preventing arthritis and all forms of carditis, but that it leaves chorea totally uncontrolled. This suggestion is also supported by the findings of the Medical Research Council. In its report it is stated that it is curious to note the preponderance of attacks of chorea over other forms of rheumatic manifestations in 60 persons whose tonsils had been removed; 36 of these developed a first attack of rheumatism some time after the removal of the tonsils and had it in the form of chorea only, four others had chorea as well as other manifestations. A. P. Thomson states that tonsillectomy is advised in all children admitted to the rheumatic hospital at Baskerville unless definitely contra-indicated, and he holds that the value of early and complete tonsillectomy in the prevention of rheumatic heart disease is definitely established.

As opposed to this view we have the statement made by Poynton at the discussion on rheumatic infection in children at the B.M.A. meeting in Bath in 1925. He said: "I know that skilled enucleation will not *prevent a first attack of rheumatism and acute* carditis of extreme severity occurring years later, and I know also that an acute and crippling attack of carditis may directly follow removal of the tonsils in the rheumatic." Wilfred Vining, dealing with debilitated and pre-rheumatic children said: "I have seen children whose debilitated state seems to date from the removal of their tonsils and adenoids, and a recent review of cases has increased my belief that the routine removal of the tonsils and adenoids is a mistake," and in his paper given at the Bath Conference he referred to children he had had under his personal observation who developed the first attack of rheumatism after the tonsils and adenoids had been removed. Hunt and Osman reviewed the after-histories of 144 rheumatic children treated at Guy's Hospital, 66 of whom had had their tonsils enucleated, and they concluded that the operation did not diminish the liability to rheumatic infection and that to operate upon apparently healthy tonsils was quite unjustifiable and could not be too strongly condemned. Among the rheumatic children investigated by MacSweeney in 12 cases the removal of the tonsils was antecedent to the first attack of rheumatism, and yet six of these children developed endocarditis. Dr. May Wilson and others kept careful records of 413 rheumatic children that were under their observation between the years 1916 and 1927, some of the cases being under observation all through this ten-year period. 247 were subjected to tonsillectomy, and the results as judged by the occurrence and recurrence of manifestations of infection after operation lead to the conclusion that tonsillectomy is not advisable as a routine therapeutic measure for the prevention of rheumatic heart disease, and that advocates of the operation do not base their claims on conclusive data.

Author's Inquiry into After-histories.

During the last two and a half years over 400 rheumatic children have been under treatment at Queen Mary's Hospital, Carshalton. With the help of Miss Mary Allan, M.A., I have made a résumé of the histories and case-notes of all these patients and the records of their progress after discharge for a certain number of the children who have been under the supervision of the London County Council. In Table I. are recorded certain facts referring to the first 300 rheumatic children admitted to this hospital, who had had no operative interference with their tonsils.

" other rheumatic signs	235	—	78·3
Deaths	17	—	5·67

In Table II. is set out information about the cases that appear to have had their tonsils removed in a satisfactory manner either before the onset or during the very early stages of the rheumatic disease.

TABLE II.—*50 Tonsillectomised Cases.*

		Per cent.
Developed endocarditis	29	= 58
„ chorea	16	= 32
„ both endocarditis and chorea	8	= 16
„ other rheumatic signs	40	= 80
Deaths	2	= 4

Over 60 cases have had to be excluded from the above tables either because the tonsils were incompletely removed or because the operation was carried out after endocarditis was established and the influence of the operation could not be fairly judged. The very variable behaviour of every case makes it very difficult to record in any simple way the complications and clinical course of rheumatism in the child. In the Metropolitan Asylums Board report of 1928–29 short case-notes of many of the patients here referred to are given, but this method is somewhat cumbersome, and it is hoped that the tables will be sufficient to indicate that tonsillectomy, even when carried out in a satisfactory manner during the early stages of the disease, does not appear to have any great influence on the behaviour of rheumatism and is no safeguard against either carditis or chorea.

THE STATE OF THE PUBLIC HEALTH.[1]

THE Annual Report of the Chief Medical Officer of the Ministry of Health for 1928, of which a preliminary review was published in THE LANCET of August 31st (p. 480), is, as usual, packed with information set out in a way which cannot fail to interest.

Sir George Newman poses six questions to which every State and every local authority must seek the answer; the State or authority which knows the most economic and effective answer will excel. These questions are: How is an imperial race to be reared? How are children to be nurtured so as to grow up into healthy and productive adults? How are healthy men and women to retain their physical and mental health, and grow in grace, knowledge, and capacity? How are the sick and diseased to be treated in such a way as to enable them to return, healed as soon as possible, to the ranks of workers and breadwinners? How, in the last resort, is disease to be prevented? How are dysgenic forces (which are undermining racial health) to be defeated, and human existence controlled? To find the answer is, he says, among the supreme tasks of government in every country; it is a problem of permeating the whole art of government with the established knowledge of science and inspiring it with humanism, a biological process which demands all the faculties and powers of man's body and mind for its accomplishment. "Preventive medicine means the organisation of human nurture. Nothing is more certain than the fact that the physical advancement and health of mankind is dependent, not upon a 'doctor's stunt,' here, or a 'sanitary institution' there, but upon the whole social environment and evolution of the people." He lays down four basic principles as foundation for a national system of preventive medicine. First there must be ascertainment and accurate registration, for without statistics we cannot even begin to measure the value of methods or results. Secondly, there must be a standard of health and physiology, and we must understand the relation of man's whole environment to the normal physiology of his body, and to departures from its standards. Thirdly, we must have an ever-increasing knowledge of the nature, character, and incidence of disease, the social factors which modify it, and its mode of spread, treatment, and prevention. Fourthly and lastly, there must be national organisation. The proof of the validity of the medical ideal is essential to its wide adoption; its acceptance depends upon the assent of the people, its application calls for public money, and its administrtion for public representatives.

Maternal Welfare.

The year 1928 was marked by considerable increase of interest in the problems that concern mother and child, and the Ministry of Health is to be congratulated on the success of its efforts to awaken the profession and the general public to the need for a more complete and adequate maternity service. The maternal death-rate has shown no substantial reduction since 1911, and although this static position may be more apparent than real, it emphasises the need for continued effort. Puerperal sepsis accounted for 1184 of the 2920 maternal deaths, and this figure must be regarded as a certain understatement of the deaths due to puerperal infection. It seems to be generally conceded that every pregnant woman should have ante- and post-natal examination by a medical practitioner, the attendance of a qualified midwife during labour, and the services of a doctor if any abnormality arises. A scheme of this sort would, it is hoped, abolish the "handy woman," and secure coöperation rather than competition between doctor and midwife. The number of antenatal clinics approved by the Ministry increased during the year, but their standard of efficiency unfortunately is not always as high as it should be. Obviously attendance at an unsatisfactory antenatal clinic may be a positive danger, and the Maternal Mortality Committee have prepared a memorandum setting forth the principles and organisation required to bring an antenatal centre to the minimum standard of adequacy. This memorandum, which was summarised in THE LANCET of August 10th, p. 295, is printed in the Report, and will, it is hoped, be studied carefully by all authorities.

There is still a shortage of maternity beds; at the end of April, 1929, there were 2480 beds recognised by the Ministry. The Report takes a conservative attitude towards the recommendation that every baby should be born in a hospital of some kind. While hoping that there will soon be enough beds to supply every woman who wants one, the Ministry feels that for a long time to come the great majority of births will take place in private houses, and that the improvement of domestic midwifery is therefore its first concern. Moreover, without an extremely high standard of treatment, and a lively appreciation of the risks of puerperal infection, the congregating of a number of parturient women in one place paves the way to an outbreak of sepsis, which could never occur if the patients were segregated in their own homes. The Report gives, as a warning, an account of some outbreaks of puerperal fever in maternity homes, and emphasises the importance of searching for unwitting carriers of hæmolytic streptococci in the nasopharynx. It is hoped that the reorganisation of space under the Local Government Act may allow for the formation of larger and better-equipped maternity units. Now that motor transport is available all over the country, one unit can serve a very large area, and small maternity homes can be linked administratively with the large centres. Although the training of medical students has greatly improved during the last decade, it is by no means universally satisfactory, and there is practically no provision for post-graduate work in midwifery. The Report urges obstetric specialists to pay special attention to this aspect of the problem.

---

[1] Annual Report of the Chief Medical Officer of the Ministry of Health for 1928–29. H.M. Stationery Office. Pp. 295. 3s.

A committee was appointed in the summer of 1928 to consider the training of midwives, and the conditions of their work. Their report will be published shortly.

The committee on maternal mortality, appointed at the same time, is a standing committee to survey the whole field of obstetric practice, and from time to time to make suggestions to the Ministry. It has three subcommittees—clinical, public health, and research. Its first duty was to advise on the investigation into maternal deaths, and two medical assessors were appointed for this purpose. The response made to the request for investigation has been very satisfactory; up to the end of last June English medical officers of health had sent in 282 reports for 1928, and 869 reports for 1929.

Infant and Child Welfare.

On April 1st, 1929, there were 2522 recognised infant welfare centres in England, an increase of 91 during the year. There are 4131 whole or part-time visitors. The new regulations making an approved certificate a condition of the Ministry's approval came into force on April 1st, 1928, and caused a certain amount of difficulty in filling vacancies. There are many more students training this year than last, but local authorities are urged to facilitate schemes for training, and to arrange attractive conditions for service. There are the same number of beds for infants as last year, and there are now 98 day-nurseries and 104 homes for unmarried mothers and their babies, 95 of which receive grants. The mothers stay about six months in the homes, which provide accommodation for 1480 women and 1340 babies. The Ministry also recognises 34 residential homes for orphaned or illegitimate babies. Arrangements have recently been made at Chailey for the reception of babies suffering from malnutrition and similar ailments; the results have been very satisfactory.

The Report remarks that the infant mortality-rate will not continue to fall unless more and more means of securing infant health are discovered and applied. The Health Committee of the League of Nations set up a committee to consider infant welfare, and under their ægis a year's investigation was made into stillbirths and neonatal deaths in selected districts in Germany, Austria, France, Holland, Norway, Italy, and England. Very much the same returns were obtained from all these areas. Everywhere the great majority of deaths fall into three groups: (1) stillbirths and neonatal deaths due to prematurity and obstetric trauma; (2) gastro-intestinal diseases; (3) respiratory diseases.

The second group is the most preventable, and can be reduced to a negligible factor in districts where care is taken. The first group accounts for about two-thirds of all infant deaths, and is not showing any appreciable diminution. Our means and methods of preventing respiratory disease are by no means adequate, and call urgently for improvement.

The time has undoubtedly arrived for a very special effort to discover and deal with the defects and diseases of children between one and five years of age. More facilities are needed, and more attempts should be made to persuade parents to take advantage of them. The most critical period is probably that of weaning and just after; the mother has neither time nor knowledge to see that the difficult process of transition from babyhood to childhood is mitigated. Frequent visits to a consultation centre are most desirable for the infant, but by no means essential for the older child, and what is needed is some scheme which will help the mother to make the best use of her own resources, and to supplement these resources when necessary. In 1924 an investigation into the health of pre-school children was initiated, with the help of medical officers of health and voluntary centres. A number of children in three groups have now been kept under observation for three years, and nearly 2000 case sheets are available for statistical investigation. The three groups were: (1) average unselected children attending a centre; (2) "catarrhal" children attending a centre; (3) two or more children in the same family. The results of an investigation at Guy's Hospital into the causes of catarrh are summarised. It was found that 1016 catarrhs were suffered by 370 children, and the greatest proportion (an average of 3·1 per child) occurred in the second year of life. The resistance during the first year is ascribed partly to breast-feeding but primarily to fresh air. The infant can be left out of doors most of the day, but the toddler needs constant supervision, and is often taken out only when the mother goes shopping. In the third and fourth years the children can be allowed out by themselves. The correlation between the amount of fresh air and the average number of catarrhs per child is very striking. Children who were grouped as having a good deal of fresh air showed an average of 1·82; those who had a moderate amount of 3·11; while those who had little air were small, pale, waxy babies, with soft limbs, protuberant abdomens and snuffling noses, or fretful toddlers with thick lips, narrow chests, poor muscles, bad appetites, and disturbed sleep, and showed an average of five colds per child.

The Insurance Medical Service.

The post-war years have formed a period of steady development of efficiency and growing mutual confidence. The Report points out once again that the "panel doctor"—sometimes criticised as though he were some strange genus—is only an ordinary general practitioner, who has chosen to devote part of his time to general practice among insured persons. The great majority of doctors in England and Wales are panel doctors, and the treatment they give their insured patients does not differ from that which they give to their private patients. The Report also explains how insurance practice can be carried out with less clerical work than is normally necessary in a well-conducted practice. The number of insured persons entitled to medical benefit in 1928 was 14,814,000, more than one-third of the total population. The number of insurance practitioners was 15,276, and the number of prescriptions dispensed by 9088 chemists was 54,455,557. Exclusive of administrative expenses, the cost of medical benefit was £9,073,080, of which about £2,241,780 were spent on medicines and appliances. The extraordinary rarity of serious complaints throughout such an immense service, which is run without any system of clinical inspection, is a striking testimony to the high standard of professional conduct which Sir George Newman believes to be "an outstanding feature of British general medical practice." During 1928, an important extension was made in the coöperation of the medical profession on the "disciplinary" side of the service. When a practitioner is adjudged by an Insurance Committee to have failed to fulfil his obligations, either party may appeal to the Ministry of Health. In considering these appeals, the Minister is now advised by a committee consisting of the Chief Medical Officer and two other medical officers of the Ministry, and three doctors selected from a panel nominated by the Insurance Acts Committee of the British Medical Association. Moreover, any officer who is appointed to hear an appeal has sitting with him a practitioner selected from this panel. During 1928, the practitioner was exonerated in most of the 209 cases of complaint investigated. Remuneration was withheld in 42 cases only, and no formal representations were made that a practitioner should no longer remain on the list. Remuneration was also withheld from eight practitioners who had failed to keep medical records, and from five who had failed to supply the regional medical officer with necessary information. It is hoped that the cost of prescribing may be reduced by the preparation of a single formulary for use throughout the country, and this formulary has now been prepared by a special subcommittee. Practitioners will also very soon be supplied with a quarterly statement of the principal statistics of his own prescribing, with a comparison of the cost per prescription per person with the average cost incurred by all the practitioners in the area.

There have been several conferences to consider the steady increase in the number of claims for benefit, and various changes in the certification rules are under discussion. It has been agreed that a common form of notice should be used for all patients who are referred to a regional medical officer, and that the source of reference should not be stated, so that patients will not know if the doctor has referred them as doubtful; that the certificates issued to doctors should be consecutively numbered, so that it is possible to ascertain the number of certificates issued by each practitioner; that statistics should be prepared of the number of patients referred to the regional medical officer by each practitioner, and of the proportion of them who consequently cease to draw benefit, and that any doctor who appears from these figures to be exercising insufficient care in certification should be approached in the matter, and that if his explanations appear unsatisfactory, the Minister should refer the matter to the panel committee for disciplinary action.

The attempt to provide post-graduate facilities met with indifferent success, and only 89 practitioners attended courses of instruction during the year. Additional efforts are being made to increase the number in 1929. More and more cases are being referred to the Regional Medical Staff, which now consists of 59 officers, eight additional deputy regional medical officers having been appointed.

By the National Health Insurance Act, 1928, two new benefits were provided: payment for medical or surgical advice or treatment outside the scope of any other benefit, and payment to approved charitable institutions for treatment outside the scope of ordinary benefit, both additions being under a special ad hoc scheme. The sum of £2,500,000 was allocated to dental benefit during 1928, and about £400,000 to ophthalmic benefit. The Regional Dental Service began its work in March, 1927, and 27,084 cases were referred to it during 1928. Two additional regional officers and 20 part-time referees were appointed.

NATIONAL VETERINARY MEDICAL ASSOCIATION.

ANNUAL MEETING AT AYR.

Dr. O. Charnock Bradley, Principal of the Royal (Dick) Veterinary College, Edinburgh, presided at the annual meeting of the Association held last week at Ayr, when delegates were present to the number of about 200, including representatives of the United States, Canada, Australia, New Zealand, and Japan. Dr. Bradley surveyed the great developments taking place in every phase of veterinary science and practice, especially the growth of animal research. In the seven years since he last presided over the Association, an Institute of Animal Pathology, under Prof. J. B. Buxton, had arisen at Cambridge, and an Animal Diseases Research Association in Scotland, with an Institute of its own. At the same time there had been a rapid and remarkable increase in the number of public appointments, the veterinary staff of the Ministry of Agriculture had been augmented, most important of all was the growth of an army of county and municipal veterinary officers The country was beginning to realise the importance of veterinary science in the protection of the health of the people. Dr. Bradley described the efforts to build up an adequate veterinary service in the colonies and dominions, where the supply was below the demand. The recommendations of Lord Lovat's committee were likely to have a profound effect on veterinary education generally. He expected that the report would induce more men of university standing to enter the veterinary profession. Uneasiness as to bovine tuberculosis was growing, and he thought the time had come to form a consensus of practical economic and academic opinion as a comprehensive basis for future action.

Carriers of Foot-and-Mouth Disease.

Mr. J. O. Powley, M.R.C.V.S., of the Ministry of Agriculture, made some striking suggestions about the sources of foot-and-mouth disease. In a recent outbreak investigated by the Ministry, lesions were found on the feet of rats. The Research Committee is pushing this point to a finish, but the viability of the virus and its easy destruction are two factors of difficulty. Feeding pigs, poultry, and cattle with crushed, imported marrow-bones has resulted in outbreaks, and presents another channel of inquiry. About 50 to 60 per cent. of the bone for making bone-meal came from South America. It was always fresh and, therefore, always dangerous. There had been reports of human beings suffering from this disease; but he knew of no steps taken to verify the diagnosis. Foot-and mouth disease is still full of unresolved problems; fortunately the incidence on human beings is small, and the "slaughter" method is practicable with animals. But something more scientific is wanted and expected.

Tuberculin Testing.

Prof. Buxton described the methods of applying the tuberculin test to herds, giving facts which, after all these years, are disconcerting. He considers that the double intradermal method gives almost 100 per cent. accuracy. The subcutaneous method is notoriously unreliable. Everyone must agree that the tuberculin itself should be standardised for animal testing as it is, under the Therapeutic Substances Regulations, for human application. Until this is done, reliable results can hardly be expected. The Medical Research Council has already surveyed the field. Obviously, too, the skill needed for carrying through the test is underestimated.

Mineral Requirements of Farm Animals.

Dr. J. B. Orr, director of the Rowett Institute for Research in Animal Nutrition, said that of the non-energy-yielding constituents, those required in largest amounts were calcium and phosphorus. They not only formed the main elements in the skeletal structures, but were present as essential components of every living cell. Pigs on a diet deficient in calcium developed symptoms resembling tetany in children, a condition in which the blood-calcium had been shown to be definitely below normal. The evidence which could be brought forward in support of the hypothesis that deficiencies of calcium and phosphorus in the food led to decreased resistance to certain diseases was much too meagre to enable them to draw any conclusions. It was sufficient, however, to stimulate further investigation. The bearing of diet on resistance to infectious disease was a research problem for human as well as for animal preventive medicine; but the most enlightening work had been done on farm animals. The field for observation was much wider in the animal world. The ideal combination for research would be team-work between the veterinary clinicians and the physiologists.

Prof. J. Russell Greig, of the Royal (Dick) College, said that the presence of calcium in the organs was of prime importance against toxins. Stiffness in race horses after the severe exercise of galloping was due to the calcium being rendered non-available. On recent evidence he had no hesitation in saying that calcium deficiency was the cause of milk-fever in cows, and he suggested that the heavy losses through sterility might be associated with the same cause.

Calcium and phosphorus metabolism are already occupying the energies of many investigators. It is pre-eminently a case for the collaboration Dr. Orr suggests. Given the adequacy or deficiency of calcium and phosphorus, the controlling factor is still to seek, just as in the case of the blood-sugar. But full advantage should and will be taken of the facilities available at institutes for animal research like the Rowett.

The next annual meeting of the Association will be held in London, before the opening of the International Veterinary Congress there, in August, 1930.

MEDICINE AND THE LAW.

Drugging the Truth out of Suspects.

A FEW days ago fresh reference appeared in an evening newspaper to the possibility of obtaining evidence in criminal trials by administering drugs to a prospective witness and thereby throwing him off his guard and enabling admissions to be extracted from him while he was at a disadvantage. This idea of applying to the detection of the criminal an experience acquired in obstetrical practice has already been discussed in THE LANCET more than once. In 1922[1] mention was made of a paper read by Dr. E. House, of Ferris, Texas, before the State Medical Association of Texas on the Use of Scopolamine in Criminology. An extraordinary attempt to turn this method to account was described in our pages a year ago when[2] "a heavy injection of hyoscine hydrobromide" was reported to have been administered to a suspected murderer in Hawaii. The Royal Commission (presided over by Lord Lee) on Police Powers and Procedure quoted our account of the Hawaii incident in its report last March in connexion with a discussion of so-called "Third Degree" methods of extracting evidence. The etymology of the expression "Third Degree" is a little obscure. According to an American authority the "First Degree" occurs when the officer of the law puts inquiries upon arrest, the "Second Degree" when the arrested person is taken to the place of confinement, and the "Third Degree" when that person has been taken into private quarters and there interrogated closely as to his movements or as to the bloodstains upon his clothing, &c. As was stated in our columns a year ago the system of extracting evidence with a hypodermic injection is so utterly alien to the British methods of police and criminal procedure that its adoption in this country is unthinkable. We have evolved an elaborate formula for warning an accused person that what he says in answers to police questions may be taken down in writing and used against him. This system of giving a "caution" is entirely inconsistent with any idea of catching a man off his guard. It has sometimes been suggested in criminal trials on behalf of the accused that the police have extracted some information from him by acting contrary to the spirit, if not also to the letter, of the prescribed procedure. Where such an abuse has occurred, there is no doubt that English juries will have seen to it that the interests of the accused do not suffer thereby. The Lee Commission was convinced that a criminal court does want to know what an accused person has said upon arrest or upon the charge being read over to him. The Commission sought to ensure that no such statement should be used at trial unless the accused had obviously been willing to make a statement and unless the statement was accurately recorded. The Commission recommended, therefore, that an accused person, expressing a wish to make a voluntary statement, should be cautioned (i.e., should be warned that he is not obliged to make any statement, but that, if he does, it may be given in evidence), should be offered writing materials, and should be left to write it without being overlooked, questioned, or prompted. If he declines to write the statement himself then—the Commission suggested—he should, as a new and additional safeguard, be required to write out in his own hand a request to the following effect:—

"I, A. B., having been cautioned that I am not bound to say anything, and that what I say will be given in evidence, wish to make a statement, which I have asked Sergeant C. D. to write down for me."

Such a request, it was recommended, should be signed by the accused person, who should add the time and date of its being written. His statement should then be taken down by the police officer in long-hand as nearly as possible in the actual words used, with a special precaution limiting the asking of questions by the police to remove ambiguities. Further, the accused should be given ample time to read and re-read his statement with a view to correction—ample time meaning several hours or even next day; and any prisoner who wishes to make a statement should, if he desires, be entitled to have his legal adviser present and to be supplied with a copy of what he has said.

These recommendations require no statutory confirmation; they merely set up a standard of fair play in administrative procedure; they do not greatly differ from the practice already operative in many of our police forces. The breadth and reasonableness of them show how impossible it is for our criminal methods to tolerate any idea of drugging the truth out of an accused person.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

Influence of Caffeine on Fertility.

Prof. H. Stieve, of Halle University, writing to the *Medizinische Welt*, reports on experiments made by him on the influence of caffeine on the procreative capacity. Using rabbits of the Russian species he made three series of experiments; in one he gave caffeine to male rabbits and then mated them with female rabbits; in another group he gave caffeine to females only and not to their mates; and in the third he gave caffeine to female rabbits who had previously been impregnated by non-caffeinised male rabbits. In the first series a quantity of 0·025 g. for each kilogramme of body-weight had no influence on the sexual impulse even if given daily for a period of six months; but of 71 young rabbits born at the proper time 54 (76 per cent.) died within the first week. Male rabbits may, however, become accustomed to the caffeine, since among rabbits receiving 0·1 g. daily all but one out of 42 young remained alive. Female rabbits are more sensitive to the drug than male ones, since in the second series 72 per cent. of the young died or were born dead. In the third series, where the females were given caffeine during pregnancy, only 72 per cent. of the expected litter were born. Of the surviving male brood some showed early disappearance of the sexual impulse. Prof. Stieve concluded that caffeine has a toxic effect on the generative glands. In females dying from chronic caffeine poisoning degeneration of the ovaries was found, while in males the formation of semen was found to have ceased. As far as man is concerned such large quantities in relation to weight as given in these experiments are never consumed. A daily consumption of 4–5 large cups of strong coffee would be less than a tenth of the quantity which poisons rabbits. But as the human species is much more sensitive to caffeine than are rabbits, the author is of opinion that regular consumption of strong coffee has a deleterious effect on the generative capacity even if it does not prejudice the general health. He believes that a part of the undesired sterility observed in many civilised nations is due to the injury done to the generative glands by caffeine together with other toxic substances. Since mental strain is liable to prejudice the sexual impulse and since brain-workers are inclined to drink strong coffee, the cumulative effect may produce sterility.

Cost of Foodstuffs.

The Hamburg Statistical Office has made an interesting research into the cost of food of an average family of the lower middle classes. They distributed household account books to 300 Hamburg families of teachers, lower grade civil servants, employees, and skilled workmen who had agreed to record daily in the appropriate columns the money expended during a year on foodstuffs. It was recorded that the nutrient value of the food was on an average adequate.

The protein foods in the form of fish, meat, cheese, and bread amounted to roughly 74·6 per cent. of the total purchase, and must be regarded as lavish according to modern views. Fat was consumed per head in a quantity of 106 g. instead of the 60–70 g. which are adequate. Of vegetables only 404 g. were taken daily instead of the 500 g. which must be regarded as satisfactory, for the cost of vegetables is not small. Every family spent on an average 347 marks for 148 kg. meat, while only 39 kg. of fish were used at a cost of 38·5 marks. This is the more astonishing, as Hamburg is situated near the sea, and the cost of 10 g. of protein in form of fish is only 5·7 pfennigs, while meat of the same nutrient value would cost 11·7 pfennigs. The Hamburg Statistical Office states that by a larger consumption of fish the importation of meat from abroad would be considerably reduced.

Prophylaxis of Diphtheria.

Immunisation of children has been going on briskly in Berlin since 1926, when an epidemic of diphtheria occurred in a rather severe form. According to a report of the Municipal Health Office, more than 100,000 children have been protected. Two kinds of prophylactic were used, the Hoechst and the Behring antitoxin. The younger the children were the better was the injection endured. Apart from the local reaction, some children showed a general reaction which consisted in an increase of temperature for 2–3 days and sometimes a rash. Very few undesirable phenomena were recorded; a paresis of the arm of a girl was reported by her mother, but could not be detected some hours later and was thus probably of a hysterical character. A boy showed swelling of the axillary glands with a passing albuminuria, and another boy had a swelling of the cervical glands with a temperature of 40° C. and hæmorrhagic diarrhœa. All these children recovered and no permanent harm was done. The morbidity of the immunised children was only one-third of the general morbidity of diphtheria. The report insists on the need for two or three inoculations, with an interval of two or three weeks between each.

Birth Injuries.

Dr. Vogel, of Leningrad, has been investigating the importance of injuries received by infants during delivery. He has communicated a full statistical report to the *Monatsschrift für Geburtshülfe* on all the deliveries in the Leningrad Maternity Hospital from 1908 to 1927. In 34 per cent. of all the deaths of infants during delivery cerebral hæmorrhage was found at autopsy and hæmorrhage of the abdominal organs in 8 per cent. of the rest, so that hæmorrhage was found in 42 per cent. Injury was the cause of death in 50 per cent. of the still-births or premature births. Injuries are especially dangerous to fœtuses with lessened resistance; in breech presentations the proportion of mortality due to injury is still higher. The prophylaxis of injuries must consist in a reduction of operations, conservative treatment being in the interest of the child as well as of the mother. The author concludes from his investigations that delivery lasting even as long as 24–48 hours gives better chances of survival than operations.

Abuse of Medical Publications.

The Syndicate of the German Medical Press utters a warning against the indiscriminate recommendation of new drugs and compounds. The committee have long ago taken measures against that nuisance so that their columns are now open only to reports founded on personal experience. Certain publishers, however, not belonging to the Syndicate, find means of recommending drugs and compounds to the profession in an unfair way. A publishing firm, for example, advertises a filing system where certain drugs are inserted with indications for their use if the producer pays a sum varying from 200 marks upwards. Another firm publishes an annual for patent medicines which, according to the prospectus, is sent free of charge to every German medical man. A medical man who runs a risk of prosecution is the editor of a therapeutic manual who sends circular letters to the pharmaceutical factories asking them whether they are willing to have their products mentioned in the manual and if so if they are willing to pay for an insertion which will not be in the form of an advertisement. The medical profession is warned against such insidious advertisement.

Accident Insurance of Medical Staff.

The recent amendment of the State Accident Insurance Laws extends the clauses of that law to the staffs of hospitals, clinics, medical laboratories, and to every person employed by a medical man as assistant (qualified or otherwise), attendant, or servant. Every medical man employing such persons is regarded as an employer under the Act and must have his personnel registered for insurance purposes. Hospitals and the medical profession form a State insurance body after the pattern of the long-existing industrial employers' associations, which have to treat and to indemnify the injured. The contributions will be low and will be collected from the individual member of the profession by the medical chamber together with the other contributions payable to the chamber.

AUSTRALIA.

(FROM OUR OWN CORRESPONDENT.)

Dr. Colin Mackenzie's Knighthood.

THE conferment of a knighthood on Dr. Colin Mackenzie has been accorded the whole-hearted approval of medical and scientific circles in Australia. Sir Colin Mackenzie has devoted the greater part of his life to an intensive study of the anatomy of the unique fauna of Australia, especially the marsupials. The anatomical structure of these mammalian curiosities presents an unequalled but diminishing opportunity for studying human embryology from the functional standpoint. Work of practical value has already been done on uterine support; the problem of the double uterus; the anatomical relationships of the ureter and genital ducts; the comparative anatomy of the mandible, the central nervous system, the colon, the great omentum, lesser sac, and appendix vermiformis. The marsupials offer an excellent field for the study of postural changes. After a brilliant career as an orthopædic surgeon, Sir Colin retired from practice in 1924 to give the whole of his time to the study of indigenous animals. He founded the Australian Institute of Anatomical Research, which controls a large reservation of native fauna in the mountainous district of Healesville, near Melbourne. His own unique collection of macroscopic and microscopic preparations—for which he recently refused an offer of £100,000—has been presented to the Commonwealth. Since the foundation of the national capital at Canberra, plans have been prepared for an Australian Institute of Anatomy, to be built at a cost of £110,000, on a site of eight acres. Associated with this institute will be a reservation of 80 acres, occupying a peninsula of the Molongolo River, where native fauna can be studied in the natural state. Canberra is destined to become the anatomical centre of the Pacific, and, from the point of view of specimens, the Australian Institute will rank second only to the Hunterian Museum of the Royal College of Surgeons of England. It is fitting that Sir Colin has now been appointed its director.

Medical Education in Victoria.

Prof. R. J. A. Berry, Dean of the Faculty of Medicine at the University of Melbourne, in a report recently submitted to the Premier of Victoria, criticises the conditions of medical education at the Melbourne University. He urges the necessity for the pre-medical general cultural education of students, for a more careful selection of candidates for the medical course, involving an entrance examination, and he considers that there is grave danger of immaturity under present conditions. Prof. Berry disapproves of the administration of the University Council which he describes as a "non-medical body of elderly men." He objects to their reviewing proposals by authorities on medical education, and he asks for increased powers of spending the money allotted to the faculty of medicine. The Council have responded to his criticism by expressing sympathy with his proposals for reform.

New South Wales Hospital Bill.

The problem of financing the hospitals of New South Wales has been the despair of their managing boards and has over-taxed the resources of the Treasury. In an endeavour to place the hospitals on a sounder basis, a Hospitals Bill has been introduced to the State Parliament. Consideration was given to the proposal to conduct a Government lottery for the benefit of the hospitals (as is already being done in Queensland) but this idea was shelved. The introduction of an amusement tax for hospital purposes was considered impracticable. The imposition of a hospitals tax was not favoured by the State Parliament. In the first place, taxation is already heavy enough, and secondly, there was a fear that nationalisation would dry up voluntary contributions and lead to a more extensive use of the hospitals by those who could afford to pay for private treatment. It is now proposed to divide the State into hospital districts and to constitute a hospitals board consisting of a chairman, two medical men, two representatives of metropolitan and country interests, and a woman member. New South Wales has been fortunate in securing the services of Mr. R. J. Love, until recently the secretary of the Victorian Charities Board, who has just returned from a study of hospitals of Great Britain and America. The board will coördinate the activities of public hospitals with a view to greater efficiency and economy in operation, will allot the subsidies in proportion to the size and needs of the hospitals, and will exercise stricter control over payments by patients who can afford them. Schemes of industrial contributions will be encouraged.

In the discussion which the Bill evoked in Parliament some interesting figures were brought to light. In 1906 there were 20 hospitals in the metropolitan area and 114 in the country. In 1926 that number had grown to 27 in the metropolitan area and 134 in the country. The number of in-patients per year for those years had been 84,800 and 116,636 respectively. The population had increased by 50 per cent., but the number of in-patients had increased by 215 per cent. The advent of motor traffic caused a considerable increase of serious cases; in many hospitals from 10 to 12 per cent. of the patients are there as a result of motor accidents, and they remain in hospital for long periods. More than 60 per cent. of the expenditure at the Sydney Hospital is on account of wages. New South Wales is making an attempt to grapple with a problem which is increasing the world over in magnitude and complexity.

ST. THOMAS'S HOSPITAL.—In his annual report Sir Arthur Stanley, the treasurer, states that, after long and careful consideration, a scheme has been evolved for the erection of an out-patient department on the site opposite the hospital purchased ten years ago. This scheme, he says, "will make St. Thomas's the finest hospital in Europe." He said that the plan which, in its entirety, includes the new medical school, had met with the whole-hearted support of the medical and surgical officers. The accommodation for paying patients in St. Thomas's Home—20 beds for each sex—is inadequate. The medical and surgical staff have represented that 80 or 100 beds would not be too many, and it is hoped that in the near future it may be possible to build such a home on the Paris-street site. Of the 593 beds in the hospital 569 were occupied on the average. There were 11,074 in-patients who stayed 18 days and cost £11 6*s.* 1½*d.* each. There were just under 100,000 new out-patients who cost 12*s.* 6*d.* each. The expenditure was £188,590, which exceeded the income by £3616.

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

THE following are some 1928 statistics of three county borough health resorts, a borough, and a cathedral city:—

Name of district and estimated (R. G.) population.	Birth-rate.	Death-rates per 1000 of the population.					Death-rates per 1000 births.		
		All causes.	Tuberculosis.	Cancer.	Respiratory diseases with influenza.	Heart disease.	Infant and neonatal mortality.	Young child (1–5 yr.) mortality.	Maternal mortality from childbirth.
Brighton C.B. (148,800)	13·5	12·9	0·91	1·09	1·4	2·7	51/27	39	2·5
Eastbourne C.B. (58,500)	12·4	11·5	0·90	1·74	1·0	2·1	43/30	15	1·4
Hastings C.B. (62,600)	12·0	15·0*	0·93	2·00	2·3	3·9	51/24	23	4·0
Swindon B. (61,110)	15·6	9·9	0·79	1·40	1·2	1·7	36/16	22	4·4
Worcester C. (52,650)	14·8	13·6	1·00	1·78	1·3	2·7	59/28	60	0·0

C. = City. C.B. = County Borough. B. = Borough.
* Standardised rate = 10·8.

Brighton.

Dr. Duncan Forbes reports that the borough was extended during the year to include Rottingdean, Ovingdean, a large part of Patcham, and a small part of Falmer. In the added areas many bungalows had been already erected with small regard to either sanitary conveniences or town-planning. The borough council have continued the arrangement made by the county council for the subsidisation of the two nurse-midwives for Rottingdean and Patcham, and with the aid of the residents a new district nursing association has been formed for Moulsecoomb. Dr. Forbes deplores the fact that children die unnecessarily from diphtheria because the family doctor is called in too late and the giving of antitoxin is delayed by waiting for the result of the bacterial examination. He pertinently asks why the examination of swabs in acute cases with exudate in children should not be discontinued. The insurance committee suggests that a rheumatic clinic should be established in Brighton.

There are still bad cases of overcrowding unrelieved. During 1928 the corporation completed 126 houses on the North Moulsecoomb estate and 60 in Whitehawk Valley. All the last-named houses are now occupied by tenants from bad property or from houses which were later occupied by tenants from bad property. The policy of the health committee was to rehouse at Whitehawk tenants from a condemned area, including some, which were not desirable, in the hope that given a chance they would improve with healthy surroundings. In 1927 a loan of £4000 was approved for the reconditioning of unsatisfactory houses purchased by the corporation. Up to May, 1929, about £3100 of this amount was spent over the purchase and reconditioning of 23 houses. On Jan. 1st, 1928, the Carlton Hill area was represented covering 3 acres and with a population of 775 adults and 228 children under 10. Brighton's difficulty is that the displaced tenants from the congested areas in the centre, who ought to be housed in the suburbs, cannot pay the increased rents and the bus fares in and out, and many of them are dirty and unsatisfactory tenants. The present scarcity of working-class houses makes a "move-round" difficult. The housing subcommittee desires to have only good tenants, and in any case the corporation could hardly rehouse bad tenants while there are good tenants living in conditions of overcrowding. The unfit houses cannot be closed and the landlords will not renovate them. Dr. Forbes puts forward as suggested remedies: that the council should consider the relief of overcrowding in sanitary as well as insanitary property in spite of the fact that the tenants cannot pay an economic rent; that a more elastic reconditioning scheme should be introduced; and that private citizens might be encouraged to form a voluntary association for the purchase and reconditioning of poor property.

During 1928 108 samples of milk were examined for tubercle and nine gave a positive result. In three cases cows were found and dealt with under the Order, but in six cases no infective cow was found.

Eastbourne.

Dr. W. G. Willoughby states that 56 subsidised houses were erected during the year, of which 46 were municipal. At the end of the year there were 986 applicants for houses, of whom 81 had a whole house, 127 were newcomers, and 130 lived outside the borough. Of the remaining 648 applicants, 115 had no child, 270 one child only, and 141 had at least three rooms each. Among the remaining 122 and the 270 with one child, there were probably about 200 instances where the council could have good tenants and remove uncomfortable existing conditions. Dr. Willoughby says that it is obviously necessary for the municipality to continue to build houses. At the close of the year only 15 of the huts were still occupied and these 15 tenants were to be provided with houses during the first quarter of 1929. The Municipal Maternity Home (14 beds) admitted 239 mothers for confinement, the total births in the borough being 726. The municipal midwife lives in the Home and attended 103 outside confinements as compared with 86 in the previous year. The antenatal work of the Home is an important development. After four years of comparative freedom from diphtheria there were 120 cases notified in 1928 with five deaths. The average notifications for the previous ten years were about 40.

Eastbourne's sunshine record (1991·8 hours) was the third highest in the United Kingdom (excluding the Channel and Scilly Islands); and the rainfall was 34·73 inches.

Hastings.

Dr. G. R. Bruce states that the chief item of interest among infectious diseases was the increased prevalence of diphtheria during the second half of the year. The peak of the incidence was in the fourth week of July with 21 notifications. The schools were not specially affected and most of the cases occurred in the populous central districts where visitors congregated. Throat swabbing indicated that the germ was widely distributed among contacts. The type of the disease was mild, there being only 2 deaths out of 133 notified cases. The orthopædic clinic at the Royal East Sussex Hospital, fully equipped and up to date in every way, was opened early in the year. At the end of the year there were 55 cases under treatment, 28 sent by the school medical, 19 by the maternity and child welfare, and 8 by the tuberculosis departments respectively. The chain of treatment appears to be complete, says Dr. Bruce, but one weak link is the difficulty in making parents understand the necessity for prolonged treatment and persistence in the exercises at home.

No subsidy houses were erected during the year and there are no municipal houses now in course of erection, although Dr. Bruce points out that there is still an unsatisfied demand for houses from families living in overcrowded rooms, basements, and small unsatisfactory houses, a considerable number of whom could not pay the rent of a council house. The first open-air school in Hastings was opened by Lord Eustace Percy on June 11th on a site previously lent by Miss Rance. The accommodation is for 25 delicate children from 5 to 9 years of age, and the education committee are considering the establishment of another similar school for the St. Leonards end of the borough. The sunshine record of Hastings was 1983 hours.

Swindon.

Dr. Dunstan Brewer reports that the borough was extended on Oct. 1st and that the Hurst municipal housing estate was included. The inhabitants of the area added had always attended the Swindon clinics and used the isolation hospital. The duties of the old Swindon and district hospital board have now been assumed by the town council and on Dec. 1st the borough took over the training school and extern midwifery department, which used to be run by the Wilts Nursing Association. The vast majority of Swindonians are reasonably comfortably housed. There are only four inhabitants per house, and if every unsatisfactory house in Swindon were swept away the population could be housed in the remainder without any overcrowding if the housing were arranged on a completely communistic basis. In practice, however, there is some overcrowding owing to the lack of lodgings for persons with families.

The great feature of the Swindon child welfare system is the continuous clinic at Eastcott Hill, where advice can be obtained every day and at all times. Ninety per cent. of the cases brought are false alarms, but the 10 per cent. represents life-saving. As an example of the value of this work, Dr. Brewer cites intussusception, which so soon becomes desperate. All stillbirths, of which there were 31 among Swindon residents, and all deaths of children under the age of 17, of which there were 66, are made the subject of investigation. This scrutiny of deaths of children has now been carried out for eight years and indicates that the mortality of childhood is now chiefly caused by measles and whooping-cough and their sequelæ. Full details of this investigation are included in the report. Dr. Brewer attributes the decrease in the neonatal deaths to antenatal supervision. The births in Swindon numbered 910, and there were 400 mothers in attendance at the antenatal clinic. In addition to the four deaths of mothers attributed by the Registrar-General to childbirth (making a rate of 4·4), there were two further deaths in connexion with pregnancy, one being from influenzal pneumonia and miscarriage and the other from gangrenous appendix. Most of the cases of ophthalmia neonatorum are treated at the municipal clinics and they are divided by Dr. Brewer into four classes:—

1. Gonococcus ophthalmia of two types, one developing within 72 hours and the other about 10 or 11 days after birth.
2. Blocking of the canaliculus. The discharge, in this case sterile, clears up after a small pellet has been pressed out of the lacrymal sac.
3. Severe ophthalmia due to the pneumococcus and other organisms. This type is indistinguishable from the gonococcal except that the cornea remains intact.
4. The fourth class includes cases associated with various micro-organisms.

Dr. Brewer gives a list of 136 cases of such ophthalmias and the organisms found during the last few years, of which 52 were due to the gonococcus. The report includes an interesting review of the epidemiology of the year. Dr. Brewer inclines to the view that tuberculosis is subject to the same general laws as are other parasitic reactions. He reiterates the view that pneumonia is of more consequence to the public health than any other factor. "If we know accurately what pneumonia is doing, we can tell the health of the community and forecast what is about to happen to it. Pneumonia, when implanted upon other infections or upon chronic disease, is the prime killer of man. From the numbers, but still more from the types, of pneumonia in Gorse Hill Hospital at any given time the health of Swindon for the immediate future can be determined with surprising accuracy."

Swindon was attacked by small-pox in 1928 having been free from this disease since 1923. In July a Swindon boy returned from South Wales suffering from an acute illness. A few spots developed and his four sisters became ill in turn, but it was not until Sept. 30th that the nature of the disease was recognised. The outbreak was divided into two periods, up to January, 1929, and from March, 1929, onwards. There was a connecting link between the two periods and the report of the whole outbreak is a matter for the next annual report. The workers in Wills' tobacco factory, who were protected by vaccination early in the epidemic, escaped entirely. The day of highest infectivity appeared to be the day before the spots appeared. Scarlet fever, Dr. Brewer points out, is at the present moment the least important of all human infections, but under local circumstances has to be isolated in hospital. An epidemic arose during the middle of the year and the only way of meeting it was to shorten the stay in hospital. About 90 per cent. (numbering 840) of the cases were treated in hospital. There were no deaths and few complications. Very few cases were detained in hospital more than 28 days and many were discharged in a shorter period than this. Nevertheless, the rate for "return" cases was lower than ever before in Swindon.

There were ten deaths from diabetes in 1928. Dr. Brewer thinks this disease is increasing, that it is becoming more a disease of females than of males, and that its incidence in childhood is increasing enormously, at all events, in Swindon.

Worcester.

Dr. Mabyn Read records an extensive outbreak of measles during the first four months of the year. There were more than 1200 elementary school-children attacked, of whom 751 were in the infants' departments. Of the 30 deaths there were two at the age-period 5 to 10, whilst the remainder occurred at the age-period under 5. The high death-rate at the 1 to 5 age-period shown in the above table was largely due to the epidemic, seeing that 27 of the 52 deaths at the 1 to 5 age-period were attributed to measles. There was no death due to childbirth during the year, and during the ten years 1918–27 there were 9002 births registered with a maternal death-rate of 2·11.

There is still urgent need for the building of more houses; 125 cases of gross overcrowding were met with and there were nearly 500 applicants for new houses listed at the end of the year. In two instances, involving 16 houses, the Housing (Rural Workers) Act, 1926, was utilised, the total grants by the local authority amounting to £590 6s. 8d. During January the Severn was in flood and the water very turbid. The water on the filter beds was frozen and the number of micro-organisms in the filtered water increased, but at no time was there more than one *B. coli* per 100 c.cm. Excepting in January *B. coli* was not found in 100 c.cm. The water in the pure water tank was treated with chlorine from Oct. 18th onwards with excellent results, which continued during February, 1929, when thick ice formed on the filter beds and had to be removed day by day.

Dr. Read records a careful effort to discover the origin of a tuberculous milk which failed. He and the veterinary surgeon took a sample of the mixed milk of 31 cows at a city cowshed, which proved to be tuberculous. The veterinary surgeon again visited the cowshed and took samples from two suspicious cows. Both were reported negative. The intradermal test was applied to all the cows and samples were taken from the six which reacted and again the results were negative. Finally the 21 cows were divided into seven groups and the seven samples so obtained were again certified to be free from tubercle bacilli.

SCHOOL MEDICAL SERVICE.

—	No. on roll.	Aver. E.S. attendance.	Routine inspections.	Special exams. and reinspections.	Percentage defects.
Gloucestershire	Not stated		13,119	7037	12·5
Nottinghamshire	53,164	46,328	10,000	22,480	27·24

E.S. = Elementary school.

Gloucestershire.

THE Gloucestershire Authority has no special schools of its own but some attempt is made to obtain accommodation in institutions belonging to others. All the completely blind and deaf children are now provided for, and Dr. J. Middleton Martin says that the committee is providing in its estimates for the education of one or two cripple children in a special school outside the county. At present there are 421 cripple children still in elementary schools. Treatment is undertaken at hospitals widely separate—for example, at Bath, Bristol, Cheltenham, Gloucester, Stroud, Stratford-on-Avon, and Chepstow. The committee has, however, established out-stations in cottage hospitals, nurses' homes, and special buildings. In 1920 it was thought that 51 out-stations would be needed, but since that date transport facilities have greatly increased so that the number required will probably be smaller. In the next three years 12 new out-stations will be established. Orthopædic cases are at present inspected by the orthopædic surgeon at the Cheltenham Hospital and at seven out-stations, and they are kept under supervision by the surgeon and by the orthopædic nurses who attend the out-stations weekly and also see as many cases as possible in their homes. Efforts are being made to interest the district nurses, who are also the school nurses, in this work, and it is hoped that they will be able to give increasing assistance in the supervision of remedial exercises and the care of appliances. There is a great need for proper education under special medical supervision and the difficulties in the way of providing it should not be insuperable. It is thought that some one person will be willing to help in the training of each cripple. It seems that the nurses who act as health visitors, school and district nurses have many duties to perform. Dr. Martin answers the objection that the district work must make it impossible for them to keep regular appointments at the schools by the statement that they have only defaulted on 15 occasions. The arrangement must improve coördination and prevent monotony, but it demands a staff fully adequate both in quality and in numbers. A sign of the efficient work done by the nurses is the distinct fall in percentage (from 16·8 in 1916 to 7·2 in 1928) of children infected with pediculi in their heads, the improvement being far more noticeable in the rural than in the urban districts. The fall is also much more marked in the older girls than in the entrants, which suggests that public opinion is having much influence in the schools but as yet little in the homes. The dental work in the past has been limited in scope; with an additional dentist and dental nurse considerable extension will be possible. An encouraging feature of progress is the rise in acceptances of dental treatment from 54 per cent. in 1922 to 74 per cent. in 1927–28.

In spite of the pressure of routine medical work it has been found possible to devote a little time to the anthropometric inquiry instituted by the Board of Education. The number of children examined was small, but the results indicate that the Gloucestershire children do not depart significantly from the average in height and weight for the whole country. Separate records kept for the children of the Forest of Dean show that they are slightly shorter than the others, the difference being possibly due to racial characters.

A special inquiry has been made into rheumatic heart disease in coöperation with adjacent counties. The research includes detailed information of the history and environment of the children, but it will be some time before a considered statement can be prepared. Preliminary examination of the records indicates a steady fall from 1921 onwards in the proportion of children affected when beginning school. Dr. Martin's general comment on the progress of school medicine in his area is that "useful as is the work already undertaken there is scope for development in various directions. Thus more centres are required for surgical examinations and intermediate treatment, especially in the southern part of the county, and provision for education simultaneously with treatment for children who cannot attend an elementary school." This is a very modest statement of the needs of the area. It is evident that good use is being made of the facilities and personnel available but that these need considerable extension.

Nottinghamshire.

Owing to the sudden death of Dr. T. E. Holmes, who "saw the School Medical Service grow from its infancy of small beginnings to its coming of age," the duty of presenting the twenty-first annual report has devolved upon Dr. A. C. Tibbits. He notes that two fundamental deficiencies mentioned in last year's report—the failure of many children to obtain spectacles and to accept dental treatment—are being dealt with on the principle of "spending more in order to waste less." Spectacles are now supplied without prepayment on the parent undertaking to repay by instalments, and expenditure is reduced by the fact that measuring for frames is done by the oculists themselves at the time of refraction. The result has been highly satisfactory, 65 per cent. of the children examined for glasses having obtained them this year, compared with 45 per cent. in 1927. Dental treatment is now given without the payment of the shilling fee when this is necessary, and much propaganda, including the display of a film, has been carried on; by these means 48 per cent. of those needing treatment have received it this year, compared with 35 per cent. in 1927. The staff of doctors and of nurses has been increased. Dr. Tibbits specifically mentions the need for accommodation for epileptics. There are no open-air schools in the county, though the number of delicate children suitable for open-air schools is given as 1303.

MENTAL HOSPITAL REPORTS.

Essex and Colchester Mental Hospitals at *Brentwood and Severalls* had, on Dec. 31st, 1928, respectively, 1745 and 1782 patients on their books. The increase at Severalls was chiefly due to transfers from Brentwood. The recovery-rate at Brentwood was 31·78 per cent. and the death-rate 8·85 per cent. Of the 94 men and 132 women discharged during the year, 172 were granted a preliminary period of trial. There was an outbreak of colitis in the spring affecting 44 women, but energetic measures cut short the epidemic, and there was only one death. Otherwise the general health was good. General paralytics are being treated by malaria with some success. A whole-time pathologist has been appointed (to serve the two hospitals), and the equipment of the laboratory is nearing completion. A new nurses' home is being erected, and plans have been prepared for a new laundry and boiler house. The hospital is being wired, and it is hoped that by the end of this year it will be supplied with electricity. During the summer 162 patients enjoyed all-day excursions to Thorpe Bay. During the year the farm and garden gave a good yield. Parole is largely granted; 434 patients are free within the grounds, and 59 outside the estate. A number of the younger female patients are taught hockey under the enthusiastic guidance of the matron, and some of them have shown a distinct aptitude for the game. Sixty-nine attendants and 38 nurses hold their R.M.P.A. certificate.

The recovery-rate at Severalls was 20·3 per cent. and the death-rate 8·1 per cent. An epidemic of typhoid during the summer attacked debilitated patients who were on a mince diet. The outbreak was believed to be due to an infection of the mince, but how this took place could not be shown. Early in the New Year a somewhat unusual outbreak of colitis occurred in one female ward, but there were remarkably few cases of influenza. Organised occupation rooms are now established for handicraft work, and evening classes are held in some of the wards. Regular gymnasium classes are held for both male and female patients, and to them the Medical Superintendent attributes the great diminution in outbreaks of violence and destructiveness. A new wing has been opened at the female hospital villa, and acute cases can now be segregated; a similar wing is badly needed on the male side. An ultra-violet ray treatment room has been equipped, and a new laboratory is to be built. Plans have been passed for a new wing on the nurses' home and an addition to the workers' villa. Fresh verandahs have been added during the year. Eighty-eight attendants and 30 nurses hold the R.M.P.A. certificate and five nurses have a general hospital training.

Hertfordshire County Mental Hospital at *Hill End, St. Albans*, had 1103 patients in its two blocks at Hill End and Arlesley on Dec. 31st, 1928. The recovery-rate was 30·4 per cent., an increase on the two preceding years. The death-rate was 7·19 per cent., including 11 deaths from tuberculosis and four from general paralysis. There is an urgent need for better accommodation. A number of men have been transferred to the Three Counties Hospital, and most of those remaining are sick, infirm, violent, epileptic, or of troublesome or defective habits. The congestion on the female side was only temporarily relieved by the completion of the new nurses' home. During the year 11 cases of dysentery, two of paratyphoid, and three of diphtheria occurred. Most of the cases were on the female side, where the overcrowding is most acute. General paralytics have been treated with tryparsamide, and suitable cases are, in future, to be inoculated with malaria. A physical drill class for male patients has been taken up with enthusiasm, and classes for raffia work and mat-making have been started in two wards. At the end of last year a canteen was opened, where patients can purchase goods by tallies. This has resulted in an increase in the amount of work done by the patients, especially in the sewing-rooms. One ward on each side is administered on the open-door principle, but only 16 patients are on full parole, and another 30 on parole within the grounds. A good deal of work has been done in the pathological laboratory, which is now well equipped. Two male and two female nurses obtained their R.M.P.A. certificate during the year, but no nurses sat for the State examinations. A mental deficiency institution is to be erected on a site in the Cell Barnes Estate, and plans are being prepared for an additional block at Hill End to accommodate 400 patients.

Cumberland and Westmorland Mental Hospital had 875 patients in residence at the end of last year. There is considerable difference between the day and night accommodation, and on the male side the hospital is overcrowded by day. The recovery-rate was 23·6 per cent. and the death-rate 7·7 per cent. The general health was good, and there was no epidemic except influenza, but the tuberculosis rate was high; 11 patients died of phthisis. All the patients discharged as recovered were allowed a preliminary period of trial. The number on parole is being gradually increased, as is also the privilege of going out for a day with nurses or friends. The chief need of the building is an up-to-date admission block for recoverable cases. Thirteen attendants and seven nurses are certificated or registered. Rather more enthusiasm for study is being shown, but there is still room for improvement.

Monmouthshire Mental Hospital at *Abergavenny* had 1209 patients on its books at the end of last year; this is one of the few mental hospitals in which, male patients outnumber female. The recovery-rate was 21·7 per cent., a figure which is much below the average for this institution, and which is attributable to the unfavourable type of admissions during the year. The death-rate was 5·2 per cent., the same as last year, and the lowest on record here. There was one case of enteric fever, a few cases of colitis, and a few of tuberculosis, but the general health was very good. The visiting surgeon was called in nine times and performed ten operations. The dentist visits weekly. All the patients are encouraged to occupy themselves in some useful way. Parole beyond the estate is given to 30 men and to 80 men and 21 women within the grounds. One ward on either side and the outlying houses and cottages are administered on the open-door principle. The laboratory is quite well equipped, and the visiting commissioners suggest the appointment of a trained laboratory assistant. They comment on the fact that there is no provision for ultra-violet ray treatment, or for cinema entertainment, and express doubt about the milk-supply. During the year 12 nurses passed their final examination.

Carmarthen, Cardigan and Pembroke Joint Counties Mental Hospital at *Carmarthen* had 651 patients on March 31st, 1929, an excess of 67 on the estimated bed space. The recovery-rate was 31·66 per cent. and the death-rate 9·14 per cent. The general health was not very satisfactory. There were 34 cases of influenza, 12 of diarrhœa, eight of tuberculosis, five of bacillary dysentery, and three of typhoid. The dentist attended weekly and treated 156 patients. The hospital is still without electric current, but the new drainage scheme and water-supply has been completed, and a new hot and cold water-supply is nearly finished. Other sanitary improvements at the farm have been effected. The dietary has been improved; butter is given in preference to margarine, but condensed milk is still used in tea and coffee. The visiting commissioner suggests the appointment of a laboratory assistant in order to bring the laboratory into activity. Great interest is taken in wireless, but more could be done to increase the patients' interest if the hospital had a cinematograph and a large motor conveyance. The farm accounts showed a loss of £117, but the profit on the garden was £216. Nine out of 11 candidates were successful in the preliminary examination for the R.M.P.A.

Glamorgan County Mental Hospital at *Bridgend* had 2032 patients on the registers at the end of 1928, an increase of 99 on the previous year, which has caused overcrowding. Fewer cases of general paralysis were admitted, but there were more chronic and congenital cases, and the prognosis was unfavourable in 65 per cent. The recovery-rate therefore dropped from 31·1 to 21·1 per cent. The death-rate of 7·8 per cent. is the lowest since 1879. Cause of death was verified by autopsy in 61·3 per cent. of cases. General health was good, except for 71 cases of influenza and three of dysentery. The visiting surgeon performed three operations and the visiting dentist 914 extractions. Although a room is set aside as a laboratory both at Angelton and at Parc Gwyllt, the commissioners do not consider that either of these rooms comply with the essentials of a laboratory. They stress the urgency of putting the laboratory in order and of appointing a laboratory assistant. Butter has been substituted for margarine, and tinned meat is now only used in emergency, but the commissioners think that more fruit and salads might be given. Cinema entertainments are held at both branches. Ten attendants and 16 nurses obtained their certificates; 57 per cent. of the men and 25 per cent. of the women are now certificated.

The Report of *Down County Mental Hospital, Downpatrick*, is illustrated by a number of photographs of the institution. There were 706 patients on the books on Dec. 31st, 1928. The recovery-rate was 30·0 per cent., a reduction on the previous year due to the very unfavourable character of the admissions. The death rate was 5.9 per cent., and autopsies were held on 21 of the 45 cases. The hospital is without electric current, which deprives the patients of several modern methods of treatment and enetrtainment. Over 100 men go outside the grounds daily, and 76 women are taken out once a week. The farm returned a profit as well as providing valuable occupation for the patients. There is no occupational therapy, but the Medical Superintendent records the impression made on him by a visit to the Dutch mental hospitals, where he found practically every patient employed. Fifty members of the staff hold the R.M.P.A. certificate, 12 having passed their final examinations during 1928. The medical staff are assisted by a visiting dentist and consultant physician, surgeon, and ophthalmologist.

MENTAL DEFECTIVES.

The Report of *Royal Eastern Counties Institution for the Mentally Defective* at *Colchester* is, as usual, abundantly illustrated by photographs of happy inmates at work and play. The Medical Superintendent makes the need for research the key-note of his report, and remarks how little foundation of proved fact there is on which to build theories of mental deficiency. The Littleton House School for mentally defective boys at Cambridge is to be attached to the Colchester Institution as a school branch. It is hoped that this will increase facilities for research. The Colchester Institution is to pay a rent to the trustees of the school, and the whole of the income accruing to the Trust is to be devoted to research. The particular type of research to be followed at any time is to be decided by a board of governors appointed by such bodies as the University of Cambridge, the Medical Research Council, the Board of Control, and the Board of Education. The very enlightened terms of this Trust are largely due to the owner of the property in which Littleton House is situated—Miss Ruth Darwin of the Board of Control.

Commenting on the advantage of sending out patients on licence, the Medical Superintendent quotes two cases of severe illness among girls living with foster-parents. Had they not been on licence, it would have been impossible to act with the promptitude necessary to save their lives. During 1928, 50 cases went out for the first time or on further trial, bringing the total to 118. Of these, two died and 23 had to return to the institution; 22 were working for wages in the care of friends, 14 were in living-in service, and 32 working at home or with foster-parents. Girls in service always spend their holidays at the seaside branch of the institution. While the year's work has been excellent, and several improvements have been made to the building, the report ends as usual in an urgent appeal for more funds to carry out necessary extensions. Applications for admission have to be refused almost daily. Two semi-detached houses and two cottages have been bought for the use of the staff, but the building of new villas has not yet been commenced. A new farm is to be added, and a house has been chosen at Witham, which, although it can only be a sub-branch, will at least accommodate 33 more adult patients. Bridge Home at Witham now houses 257 patients of the lowest grade. An idea of the work here is given by the statement of the Medical Superintendent that during the year the staff had to deal with 4749 wet beds, 1157 dirty beds, 1922 boys dirty in the day-time, and 2516 epileptic fits. The number of fits has been greatly reduced during the last few years by the use of luminal. The various shops all did excellent work and made good profit. The brush shop made 9123 brooms and brushes, and the shoe-shop made 300 pairs of new boots, as well as doing all the repairs for the branch—over 30,000 pairs. The School Guides and Brownies have now taken 300 second-class and proficiency badges, and although there is no compulsion every girl in the school belongs to the company or pack. The frontispiece of the report is a photograph of part of the company, which appeared—to everybody's immense delight—on the outside cover of "The Guide," the official organ of the Girl Guides Association. The scouts have already won 23 badges, and the team came out fourth on the list for the Ambulance Shield. Attempts are being made to get more boys working in the garden, as those who go out will probably have to earn their living on the land, and the Medical Superintendent feels that a boy can be kept too long doing simple handicrafts which he has completely mastered. The institution has now begun to act as a day school as it was obviously uneconomical for the local authority to open a day-centre with the Royal Eastern Counties Institution so near. There is very little illness among the children. One cold February day there were 20 patients in bed out of 1100 in residence. Nursing a mental defective, therefore, is chiefly a matter of being able to teach a child to keep clean and happily occupied, and the Medical Superintendent welcomes the extension of the R.M.P.A. examination to include proficiency in any one of four main sections of the work of a big modern institution. The death-rate was 1·74 per cent., which includes two deaths of patients who had been on leave of absence for a year or more. The tuberculosis death-rate was 0·58 per cent., a remarkable drop from 4·6 per cent., which was the average figure from 1859 to 1904. Since a general Schick test in 1925, and the immunisation of all susceptibles, there have been no cases of diphtheria.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED AUGUST 31st, 1929.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 131 (last week 139); scarlet fever, 1833; diphtheria, 850; enteric fever, 84; pneumonia, 522; puerperal fever, 64; puerperal pyrexia, 114; cerebro-spinal fever, 16; acute poliomyelitis, 24; encephalitis lethargica, 20; continued fever, 1; dysentery, 5; ophthalmia neonatorum, 128. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on Sept. 3rd–4th was as follows:—Small-pox, 165 under treatment, 8 under observation (last week 144 and 24 respectively); scarlet fever, 1335; diphtheria, 1405; enteric fever, 18; measles, 311; whooping-cough, 220; puerperal fever, 23 (plus 8 babies); encephalitis lethargica, 124; poliomyelitis, 1; "other diseases," 18. At St. Margaret's Hospital there were 13 babies (plus 5 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 2 (0) from enteric fever, 20 (0) from measles, 6 (2) from scarlet fever, 22 (4) from whooping-cough, 19 (4) from diphtheria, 78 (10) from diarrhœa and enteritis under two years, and 18 (2) from influenza. The figures in parentheses are those for London itself.

Of the deaths from diarrhœa (the fewness of which is gratifying) 8 were reported from Liverpool, 6 each from Birmingham and Hull, 5 from Sunderland, 3 each from Portsmouth, Southend-on-Sea, Leeds, and Gateshead. The deaths from enteric fever occurred at Southport and Cardiff.

The number of stillbirths notified during the week was 267, corresponding to a *rate* of 40 per 1000 total births, including 46 in London.

THE LONDON HOSPITAL.—The House Committee reports that last year the in-patients numbered 14,049 and stayed on the average 17·67 days. The out-patients numbered 70,962 and a further 25,966 persons suffering from minor ailments were dealt with in the receiving room. The income was £316,000 and the expenditure £276,000. In-patients cost £5 13*s.* 5*d.* each and out-patients 15*s.* 6*d.* The report for the quarter ending August 31st states that the radium department is now in working order. The radium is kept in a safe in a strong room, encased in 7¼ tons of lead. The gramme of radium which has been delivered is being used for the making of radon, but as more can be made than is actually required arrangements have been made for supplying it, at a charge, to other hospitals and to members of the staff for private cases. A second gramme will be delivered shortly in the form of needles.

Obituary.

SIR SEYMOUR SHARKEY, D.M. OXF., F.R.C.P. LOND.

THE death of Seymour John Sharkey at his home in London removes almost the last of a band of men to whom the school of St. Thomas's is indebted for its re-establishment in the honourable position it held prior to the temporary eclipse occasioned by its migration from Southwark to Lambeth.

SIR SEYMOUR SHARKEY.

Photo by Elliott & Fry.

Seymour, one of the three talented sons of Dr. E. P. Sharkey, an Irish medical man, was born in 1847. Educated at Christ's Hospital, he gained a classical scholarship at Jesus College, Oxford, of which College he was elected an honorary Fellow in later life. His inclinations passed at an early period from classical study to that of science, and he gained a first class in the honour school of natural science. He thus came under the influence of one of the masters of modern biological research, Prof. G. Rolleston, F.R.S. Sharkey became one of Rolleston's demonstrators, and this association without doubt remained a lasting influence both on his line of thought and his conception of what the life of a physician should be. His Oxford career ended with his election to a Radcliffe Travelling Fellowship in 1873, and his medical life commenced with experience gained in continental universities, particularly in Germany, followed by entrance at the school of St. Thomas's Hospital. After qualification in 1875 he became resident assistant physician to the hospital. At the termination of his period of office he was much shaken by the death, attributed to overwork, of one of his brothers, so much so that it was thought advisable by his friends that he should seek an absolute change of occupation and surroundings. Hence he spent some time travelling abroad, returning later to be elected assistant physician to the hospital. This episode is worthy of mention because it explains the rigid rule, maintained for the rest of his life, not to allow any consideration to compel him to see more than a certain number of patients daily or to interfere with his week-end relaxation.

Once elected on to the staff of his hospital Sharkey's energies were devoted largely to the work of the institution and to the furtherance of medical education. His teaching was well informed, sound, and effective, and many generations of students retain grateful memories of the help they received from him. He was certainly for a long period the most popular teacher in the school. The work of the hospital was performed with energy and precision. Visits were never missed, never commenced late, or terminated too early, and Sharkey gave confidence to the patients, to the juniors, and to the nursing staff; by all he was respected and indeed beloved. His interests were with medicine in general, but in his early days he acquired a reputation for special knowledge as a neurologist as a result of clinical observations connecting localised disease of the brain with definite symptoms and signs, and this work justified his later election as President of the Neurological Society. Admitted a Member of the Royal College of Physicians in 1879 he became a Fellow in 1885, and in the following year delivered the Goulstonian lectures, on Spasm in Chronic Nerve Disease, which were published in THE LANCET. His subsequent association with the Royal College of Physicians was intimate, for he acted as examiner and served the College as Censor for some years, becoming Senior Censor in 1912. In 1906 he delivered the Bradshaw lecture on "Rectal Alimentation" (THE LANCET, 1906, ii., 1203). He was knighted in 1914, but declined a second honour offered him for his services when he retired from office as medical referee to the Treasury.

Sharkey was above all things an enthusiast in clinical medicine. More than any other part of his work he loved teaching, and his pupils of all degrees, and over many generations, recognised and appreciated his efforts, though they sometimes smarted under his incisive tongue. He will be remembered with gratitude and affection in many parts of the world by a wide circle of those who profited by his teaching or were inspired by his example. Sir George Makins, for whose recollections of Sharkey's earlier career we are indebted, sends us the following personal note.

Sharkey's choice of St. Thomas's as his school was determined by the reputation of Charles Murchison as a clinical teacher, and his own method was no doubt founded on the lines adopted by Murchison. St. Thomas's, however, at that period was fortunate in the possession of a gifted clinical teacher of a more philosophic turn of mind, John Syer Bristowe, and it is probable that a just comparison between the methods of the two men preserved Sharkey from the superlative dogmatism which dominated Murchison's teaching. Murchison's method was perhaps ideal for candidates preparing for examination, Bristowe's for enlarging the man's horizon and creating a proper scepticism regarding certain received beliefs. With Murchison an answer was either right or wrong; Sharkey, while adopting Murchison's precision, was always open to argue the point, and in such discussions he delighted. His pupils had a certain fear of his sarcasm and were not always convinced by his reasoning. A characteristic example of his sense of fairness and right in the management of his school was exhibited shortly after his appointment to the assistant staff. At that time the entire sum derived from the fees of the students after the expenses of administration had been deducted was divided amongst the members of the senior staff. Sharkey and his immediate surgical colleague, Clutton, attacked this arrangement with great vigour, and it is of interest to recall that they only carried the day when on election to the senior staff they acquired sufficient influence to bring about a change by which they suffered personal loss.

No sketch of Sharkey would be complete without mention of two friends who materially influenced his habits and career. His association with H. H. Clutton commenced with their respective appointments as senior residents at St. Thomas's and persisted until Clutton's premature death. Until Clutton's marriage they lived together. There was little resemblance between the two men; Sharkey was of a philosophical turn of mind, Clutton eminently and severely practical, and this diversity perhaps explained the permanence of the association. The two men never wearied of discussing and arguing on any subject which interested them. Sharkey was one of the early physicians to welcome the aid of surgery, and a bedside consultation between the two men was a source of real pleasure to their respective classes. When a difference of opinion arose the two chiefs would attack each other with freedom and familiarity, and doubts as to who would be the winner enlivened the audience. His other most intimate friend was Sir George Savage, who was the companion of his hours of relaxation. They fished, played golf, and gardened together. Sharkey was an expert dry-fly fisher and could bring home trout when no one else could find or lure them.

Sharkey maintained a semblance of unchanging age until some six months before his death. He was never married, but he delighted to entertain in his charming home. It was as a host and also at the meetings of a small dining club, of which he remained a member to the end of his life, that his social talents showed to best advantage. In his last years he was to be found on most afternoons in the smoking room of the Athenæum reading and chatting with his friends. Sharkey's strict sense of honour, absence of any shadow of self-seeking, and conscientious fulfilment of the duties he undertook brought him many friends and gained for him the respect of all those with whom he was associated.

Dr. T. Dyke Acland writes: I first knew Sharkey when he was an undergraduate at Oxford. He was then, as he remained all his life, full of fun, active, energetic, and enthusiastic. He carried his vitality into his work as well as into his play. Wherever he was he gained for himself the affection and confidence of his teachers, friends, and fellow students. At Oxford he came under the influence of Sir Henry Acland, Sir J. Burdon Sanderson, and Prof. Rolleston, and remained on terms of intimate friendship with them all until their deaths. It was under the direction of the Regius professor that he commenced the practical work in a clinical laboratory which he later developed so successfully at St. Thomas's Hospital. Throughout his career Sharkey was always ready to help and advise those who were in difficulty, and though some found his manner brusque and his criticisms outspoken, he was recognised to be a wise counsellor whose opinions should not be lightly disregarded. Sharkey had a strong and vigorous personality. He spent his life doing that which he believed to be right, and spoke the truth from his heart.

FREDERICK FOORD CAIGER, M.D., F.R.C.P. LOND., D.P.H.

Dr. Foord Caiger died rather suddenly on Sept. 5th while on holiday in Scotland, and his death will leave a blank in the lives of a large circle of friends and colleagues who had found in him a wise clinician, an able administrator, and a loyal friend.

Frederick Foord Caiger was born in December, 1860, the son of Frederick Henry Caiger, F.R.I.B.A., architect to the Metropolitan and City Police. He was educated at Westminster School and St. Thomas's Hospital, where he was Mead medallist, and from which he qualified in medicine at London University in 1883, being awarded the gold medal in surgery and honours in other subjects. Three years later he took the M.D. Lond., and shortly after the D.P.H. Cambridge. He held three house appointments at St. Thomas's Hospital, and five years after qualifying entered the service of the Metropolitan Asylums Board as assistant medical officer at the Northern Fever Hospital, where his work was such as to lead to his appointment as medical superintendent of the South-Western Hospital, Stockwell, before he was 30 years old. This office he held continuously until October, 1926, when he retired from the service of the Board after an association of 30 years. For the last five years of this period he was chief medical officer of the whole infectious hospital service, and was called upon to guide the policy of the Board in such matters as the best allocation of beds among the various kinds of infectious fevers, the employment of the new immunity tests, and the early administration of antitoxin in diphtheria.

In 1921 Caiger was appointed emeritus physician to St. Thomas's Hospital. As a clinician and a teacher he then had a reputation, both within his own hospital and outside, which was second to none. He was clinical teacher in fevers to the R.A.M.C., and it was a tradition with St. Thomas's students that their fever course should be taken with him at the South-Western Hospital, where, unless application were made at the earliest possible moment, there was but little chance of getting on the list. His lectures were lucid and stimulating, and his clinical demonstrations first-rate. Caiger was always abreast of his subject, and readily adopted any innovation of value, be it for diagnosis, treatment, or prevention. But he never lost the sense of perspective, and we have many testimonies to the excellence of his advice and the soundness of his diagnosis. Although he never published a text-book on fevers, Caiger was much in request as a writer on his subject, and his contributions to Allchin's Manual, Quain's Dictionary, and Allbutt's System are well known. He was always ready to accede to the requests of local medical societies and of the Medical and Physical Society at St. Thomas's for an address on some topic of interest connected with his specialty. His interest did not lie only with the clinical side of medicine; like all good clinicians he recognised pathology as the basis of sound clinical advance, and it was on his advice that the Board in 1925 appointed a Director of Research and Pathological Services, and decided to establish two thoroughly equipped group laboratories. Caiger was the first chairman of the Scientific Advisory Committee set up by the Board, after consultation with the Medical Research Council, to advise on the extension of knowledge by research and the full and prompt application of available knowledge to fever practice. He was a member of the Antityphoid Inoculation Committee appointed by the Army Council in 1904 and played a large part in the long and difficult investigations involved in the preparation of their report. In his Bradshaw lecture, delivered the same year before the Royal College of Physicians of London, he gave a masterly survey of the treatment of enteric fever as then practised, registering his conclusion that any further advance in treatment must be sought in biological sources.

DR. FOORD CAIGER.

Photo by Elliott & Fry.

Caiger possessed in high degree the qualities required for successful administration and organisation, and these stood him in good stead when he was commissioned to open the Fountain Hospital during an exceptional incidence of scarlet fever in 1893, and six years later when 500 beds were provided at the Grove Fever Hospital to meet an unusually high seasonal rise of enteric fever. He took a personal interest in the welfare of the hospital staff generally and individually, and succeeded in gaining their loyalty and devotion and in no small degree their affection. It was largely owing to him that the Fever Nurses Association was founded. He was its hon. treasurer from the start and at one time its president. Caiger's relations with his fellow practitioners in his neighbourhood were cordial and intimate. At St. Thomas's it was to him that application was made for assistance in the thorny problems of accidental infections, and many a resident had reason to be thankful for his ready help and solicitous treatment. Local practitioners found him sympathetic with their difficulties and tactful with their mistakes. "We all learned," one of them writes, "to come to him, knowing full well that he at least would never make us feel that we had been grossly stupid or unobservant." "Among Caiger's charms," another writes, "was a natural and sympathetic consideration for everyone with whom he worked. The only way to make him bristle aggressively was to suggest some adverse criticism of his staff or of the Board to which he was loyalty itself. Any lack of consideration to a subordinate would promptly arouse his condemnation; at the same time he was magnanimous in his praise of any effort to do the right thing."

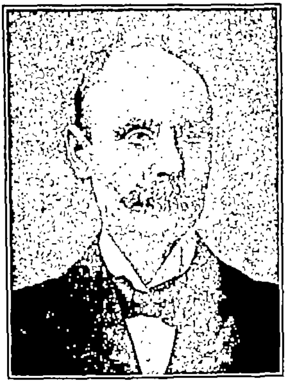
On his retirement from the Metropolitan Asylums Board three years ago, Caiger's help remained available to private practitioners in their clinical problems. He remained active on the Governing Body and Executive Committee of the Enham Village Centre for the curative treatment and training of disabled ex-Service men, to the organisation of which he had given much time and thought. Of his personal characteristics little more need be said than what has appeared in connexion with his professional work. His tastes were simple and he had a deep appreciation of natural beauties which made his companionship on foreign travel pleasant and stimulating. He was a good impromptu speaker, with just the right touch of hesitation in choosing the appropriate phrase or illustration which always came. He lived, as one of his friends puts it, every moment of his life to its fullest and best.

Dr. Caiger married in 1895 Madeline, daughter of Alexander Orr, a landed proprietor in Australia, who survives him. Their only son was killed on the Western front in November, 1916.

SIR JOHN CAMPBELL, M.D., M.CH., LL.D. R.U.I., F.R.C.S. ENG.

Sir John Campbell, who died on August 31st at his home in Craigavad, Belfast, was born in 1862, being a son of the Rev. Robert Campbell, of Templepatrick, Co. Antrim. He was educated at the Royal Belfast Academical Institution and at the Royal University of Ireland, and also studied in London and abroad. He took a degree in biology with first-class honours in 1883 before turning to medicine, when he gained a scholarship in therapeutics and pharmacology and the Coulter exhibition at the Belfast Royal Hospital. John Campbell qualified and proceeded to acquire the higher degrees in medicine and surgery in quick succession, becoming F.R.C.S. Eng. in 1891. He served as demonstrator of anatomy under the late Prof. Peter Redfern for five years, and for a time held the post of assistant surgeon to the Belfast Hospital for Sick Children. Later he took up gynæcology and obstetrics, and became consulting surgeon to the Maternity Hospital for Women. His name is chiefly associated with the Samaritan Hospital for Women, to which institution he was attached as surgeon, and later as senior surgeon for many years. He worked hard not only to establish the prestige of this hospital but to raise that of his specialty throughout Ireland, and succeeded well in this task. His publications included successful text-books as well as original articles. In 1909 John Campbell's services to medicine were recognised by the honorary degree of LL.D. of the Royal University of Ireland. When the Northern Parliament was formed in 1921, he was elected as one of the four Unionist Members for Queen's University, and he sat in the House until Parliament was dissolved this year. At the time of his death he was Chairman of Convocation. During the war John Campbell acted for a time as surgeon to No. 5 British Red Cross Hospital at Wimereux. He was knighted in 1925.

Prof. Andrew Fullerton writes: "The passing of John Campbell removes an outstanding figure from the community of Northern Ireland, where he has occupied a prominent position for a period of nearly 40 years. A man of great ability, wide culture, and transparent honesty, he commanded the admiration and respect of a large circle not only in his own country but far afield. His industry at the Samaritan Hospital and in practice, regardless of financial return, brought its reward, and in a few years he gained a reputation for ability, skill, and judgment which most men take long to attain. His success as a surgeon did not spoil him, and he remained the same modest, unassuming rock of common sense who had impressed his fellow students in his undergraduate days. Few medical men of his time have not at some period of their lives confided their troubles to him, and sought and obtained his sage advice. In the Parliament of Northern Ireland he proved himself a wise counsellor whose opinions carried weight with politicians of all sides.



SIR JOHN CAMPBELL.

"To the public, he was a man of few words, downright in his manner of expressing himself, and to all appearance stern and reserved. To the inner circle, however, he was a most charming companion. His education had been conducted on liberal lines and he had a mind well stored with information, but his strong sense of humour saved him from imparting more than would interest or entertain his listeners. A superficial observer might have thought him unsympathetic, but those of us who were intimate with him knew that he had a kind and sympathetic heart. He was greatly affected by his war experience. I remember when he first came to France, meeting him at the boat and taking him to visit some of the hospitals, to show him the kind of work he would be expected to do. At the end of the first days he felt the strain badly, but he carried on and did good work. His colleagues at No. 5 British Red Cross Hospital will hear with great regret of his death and will think of him with the kindest memories and with warm appreciation of his services."

PERCY CHARLES WOOLLATT,

F.R.C.S. EDIN., M.D. BRUX.

Mr. Percy Woollatt, who died recently as the result of a motor accident in Normandy, was younger son of the late Mr. S. P. Woollatt, J.P. for Hertfordshire. He took the conjoint qualification from the London Hospital in 1905, later adding the M.D. Brux. and the F.R.C.S. Edin., and entering the Indian Medical Service was stationed at Shiraz, where he had charge of the Indian Government Hospital, and was medical officer to the telegraph department. Later he was surgeon to the Imperial Hospital at Teheran, and his surgical skill became notorious throughout Persia, securing him a freedom of movement in a dangerous country which was denied to many of his colleagues. On the outbreak of war in 1914 he volunteered for service in the navy and was appointed to the Haslar Hospital. On his return to South Persia it was as surgical specialist to the Forces there until 1920, when he retired from foreign service and took up general practice at Hinckley, Leicestershire, with charge of the Cottage Hospital. Lately he was consulting surgeon in London. His elder son is a medical student.

DR. WALTER ERICHSEN (ERIC) POWELL, who died on August 31st, as the result of appendicitis, was in his 35th year. He was educated at Brighton College and Charing Cross Hospital, qualifying M.R.C.S. in 1917. He then joined the navy and was appointed to a "Q" boat in which he saw service in the Mediterranean. When the Armistice was declared he returned home to join his father, Dr. W. A. Powell, in practice at Brighton. He was anæsthetist at the Brighton Poor-law Infirmary, and deputy anæsthetist at the Throat and Ear Hospital. He also acted as deputy police surgeon. He leaves a widow, who was formerly a sister at Charing Cross Hospital, and six children.

Correspondence.

"Audi alteram partem."

ON RESTARTING THE HEART-BEAT.

To the Editor of THE LANCET.

SIR,—Experiments I carried out on cats six or seven years ago showed that the heart could be restarted (and could thereafter raise the blood pressure to 100 mm. Hg) even so long as an hour and sometimes two hours after it had ceased to beat (B.P. = 0). The method employed was intracardiac injection of adrenalin along with either artificial respiration or instillation of oxygen into an artery—generally the femoral, using the profunda femoris as a cannula. Spontaneous breathing was never resumed if the B.P. had been nil for over 15 minutes. If the heart had completely ceased beating for only 5–10 minutes, then natural respiration might reappear, but the cat (though it sometimes lived for 24 hours) was never normal, and in behaviour closely resembled a decerebrate animal.

From all my observations I concluded that if the circulation had entirely ceased (B.P. = 0) for five minutes, the cerebrum never revived. After ten minutes the central nervous system was dead down to the pons, after 15 minutes down to the calamus scriptorius. It seems therefore hopeless to look for complete recovery of all the faculties in man if the circulation has entirely ceased for even five minutes, and restarting the heart and continuing artificial respiration if the heart has ceased to beat for so long as 15 minutes is a useless waste of energy. In cases in which complete recovery has been reported at later periods, probably the circulation had not, in fact, entirely ceased.

The lesson to be learned from these facts is that cardiac massage, adrenalin injection, and artificial respiration must be applied at the earliest possible moment if valuable results are to be attained, and that they should be resorted to in all cases where the heart seems to be stopping before actual cessation has occurred.—I am, Sir, yours faithfully,

THOMAS LUMSDEN.

Lister Institute of Preventive Medicine, London, S.W.,

CEREBRAL LOCALISATION.

To the Editor of THE LANCET.

SIR,—In a short notice in the last issue of THE LANCET of a book by Dr. R. Brugia, the reviewer seems to treat the ideas put forward by the author as something new, and asks pertinently: what is meant by "centre" and what by "localisation"? On the clinical side Marie, working at the same hospital as Broca but with a more extensive choice of subjects, proved that Broca's theory of localisation was untenable. His positions are set forth in the work of Dr. F. Moutier, "L'Aphasie de Broca." Prof. von Monakow in his "Über Lokalisation der Hirnfunktionen" arrived at conclusions concordant with those of Marie. Since then many authors, notably a school of Italian physicians, have further subjected Broca's theories to a destructive criticism.

In 1912 I published my "Psychology: A New System," in which on purely psychological grounds—borrowing from physiology only the hypothesis that the development of the brain has been "economic"—I made it clear that it could not be stated categorically that Broca's theory was right or wrong, for the whole conception that underlay his localisation was faulty. The demonstration that I offered found confirmation in Marie's observations, but it should be looked upon rather as giving the necessary underlying explanation of the results at which that great neurologist had arrived. The methods I employed were the developments of the elaborate analysis on which I based the entire system of my psychology; but an indication may be given which will show that Broca's theory of aphasia is inconsistent even with that of the "centres" involved. The analysis of any word, when its meaning is fully comprehended, would imply the activities of a series of "centres" corresponding to visual, aural, tactile, and muscular sensations, and this fact in turn implies connecting nerve paths sufficient to supply the necessary associations. Thus we find that remote though associated parts of the brain are in activity during each movement, however simple, of consecutive ideas, and this activity is not merely that of primary excitation but also of corresponding inhibitions. As Sir William Gowers remarked, the brain is not like a piano, but rather like an organ; I would say, it is more like an elaborate system of charged telegraph wires.

Now, to represent the matter strikingly, I submit that when our histology has been perfected and our physiological psychology further advanced, then, with delicate instruments, it would be possible, without touching the third left frontal convolution, to produce not only Broca's aphasia but a veritable assortment of aphasias. The proper image to be formed is not that of "centres," but of a complete system of interrelated activities. What has been called a centre is not a terminal station, but, to use von Monakow's expression, a gate.

I am, Sir, yours faithfully,

ARTHUR LYNCH.

Haverstock Hill, N.W., Sept. 6th, 1929.

EFFECT OF X RAYS ON BLOOD PLATELETS.

To the Editor of THE LANCET.

SIR,—In a paper by Dr. Samson Wright and Dr. H. A. Bulman, published in your issue of August 3rd (p. 217), on the Selective Action of X Rays on the Blood Cells of the Cat, some observations on the effect of irradiation with X rays on the blood platelets show a substantial agreement with similar observations on the effect of gamma rays from radium, published by us in 1922.[1] Instead of drawing attention to this agreement Dr. Samson Wright and Dr. Bulman give an incorrect account of our results and conclusions and state that their results are contrary to our experience In view of the importance of the subject and of the promise of a more detailed publication by them it may therefore be well to restate briefly our results.

We found in experiments on rats that exposure to gamma rays produces a thrombopenia. If the doses were moderate—i.e., sublethal—the number of platelets shows a rapid spontaneous recovery to the normal. Dr. Wright and Dr. Bulman found the same after exposure to X rays. If the dosage of gamma radiation was increased we found that the number of platelets did not rise again, an anæmia developed, and the animals died. In our experiments the animals died in the third week—later than in the experiments of Dr. Wright and Dr. Bulman. At death our animals exhibited signs of a general infection. Our experimental observations agree with the clinical observations that cases of pernicious anæmia have occurred among radium workers. In these human cases there has also been evidence of a general infection. Between the observations on rats with radium and on cats with X rays there is, therefore, complete agreement on the main point that large doses of irradiation produce a diminution in the number of platelets.

An apparent discrepancy is presented by the platelet counts of two cats in Dr. Wright and Dr. Bulman's series which died or were killed on the seventh and tenth day respectively. Both these animals were heavily infected but the platelet count was stated to be "normal." It was 1·5 millions in one animal, 0·75 million in the other. Dr. Wright and Dr. Bulman comment on these findings by saying that they are "contrary to the experience of Cramer, Drew, and Mottram with the rat, who found a marked decrease in the platelet count following gamma radiation in animals that died of intercurrent infections." On this point we wish to remark, first of all, that we did not make the statement in this form. We found a decrease in platelets following gamma radiation whether the animals died of intercurrent infections or whether they survived. Secondly, our animals died after a much longer period after exposure (17–20 days) than the cats of Dr. Wright and Dr. Bulman (7 and 10 days). Since in their surviving animals the onset of the thrombopenia did not begin until the twelfth day, the two cats with a count stated to be normal died before the thrombopenia had time to develop. Lastly, the authors state that the platelet count of normal cats in their series varied from 0·75 million to 5 millions. No such wide variations are found either in normal rats or in man. If this statement is correct it would suggest that cats are not the most suitable animals for the study of variations in the number of blood platelets.

We are, Sir, yours faithfully,

W. CRAMER,
J. C. MOTTRAM.

DISINFECTANT PACKETS.

To the Editor of THE LANCET.

SIR,—Dr. Earp's letter in your issue of Sept. 7th (p. 530) has drawn my attention to a quotation in the report of my remarks at the Fourth Imperial Social Hygiene Congress (THE LANCET, 1929, ii., 140) which may give rise to a misunderstanding. In quoting the statistics mentioned I applied the expression "for what it is worth" to my remembrance of the figures, mentioning that I was speaking from memory, and promising to bring the original documents to the next session in order that those interested might verify the figures. Unfortunately, your necessarily abbreviated report of the proceedings has made it appear that I applied the expression "for what it is worth" to Prof. Queyrat's figures—which was far from my intention. These figures and others bearing on the same question, to which I would refer Dr. Earp, can be seen in *Mouvement Sanitaire* (1927, iii., 607–15), and in Prof. Queyrat's address before the Assembly of the Union Internationale contre le Peril Venerien, Nancy, 1928. (Texte des Rapports, p. 50.)

I am, Sir, yours faithfully,

S. NEVILLE ROLFE,
Secretary-General.

Carteret House, Carteret-street, London, S.W.,
Sept. 9th, 1929.

[1] Proc. Roy. Soc., 1922, xciii., 449.

COUNTY MEDICAL OFFICERS OF HEALTH IN IRELAND.

THE *Department of Local Government and Public* Health of the Irish Free State is pressing for the appointment of county medical officers of health, and it is understood that four or five appointments will shortly be made. Our local correspondent informs us that several counties are still reluctant to take action. For example, the South Tipperary County Council and Board of Health have passed resolutions protesting against the proposed appointment of a county medical officer as expensive and unnecessary, having regard to the existing dispensary doctors. The Leitrim County Council has adjourned the consideration of the question on the grounds that the appointment is unnecessary. One member of this *council expressed the opinion that there was no sense* or reason in appointing a county medical officer of health when the children of the county were underfed and underclothed. Before they looked after the eyes and teeth of the children they should see that they were properly fed. It is clear that the country is still badly in need of education on the value of health to the community. Apart from the delay in making appointments Ireland's sanitary administration has to face another danger. The salaries offered for county medical officers of health are small, and are not likely to attract men of adequate experience. There is a grave danger that men with paper qualifications only, and without practical experience, may be appointed. Up to the present there has been no public health system in force in Ireland, so that Irish medical men have had little opportunity of gaining experience in their own country. The best hope of acquiring experienced administrative officers may be to attract candidates who have worked in England or elsewhere, but the salaries offered are not likely to achieve this result.

LABELLING OF POISONOUS SUBSTANCES.

ON August 10th, at Shoreham (Sussex) Petty Sessions, a grocer and provision merchant of Lancing was summoned for selling a certain quantity of carbolic disinfectant, containing not more than 3 per cent. of phenol, enclosed in a wrapper that was not distinctly labelled with the words "Poisonous, not to be taken," and did not have the name and address of defendant as the seller thereon. The defendant pleaded not guilty. Evidence of the purchase was given by a representative of the Pharmaceutical Society, who stated that *she drew the defendant's attention to the fact that his name should have been on the bottle and that he* agreed. She also pointed out that there were also no words to indicate that the contents were poisonous and were not to be taken. The defendant's solicitor produced a bottle and removing the wrapper asked witness if it did not say on the bottle, "Poisonous, not to be taken." Witness agreed, but said it contained no name and address of the seller. The Magistrate's Clerk: "Technically speaking, it should be on the wrapper." Defendant's solicitor said the section of the Pharmacy Act provided that it should not be lawful to sell any substance to which the section applied unless the box, bottle, vessel, wrapper, or cover in which it was contained was labelled with the name of the substance and the word "poisonous." Hence it was only necessary for one or the other to be so marked, and as the label appeared on the bottle the Act was complied with. He added that the bottle revealed the name of the seller—namely, the makers of the solution. The police superintendent pointed out that the Act meant by the seller the person making the sale. The sale was admitted. This lysol solution, said the defendant's solicitor, was barely poisonous, because it contained something less than 3 per cent. of carbolic, but apparently it came within the Order under the Act. Possibly his client had made a mistake in regard to not having his own name and address inscribed. The manufacturers of these substances, as a rule, warned the retailer at the time of purchase that the name of the retailer must be added when the substance was sold to the public. In this case no warning was received, and his client did not know that the substance fell under the Act. The defendant had been in business for 35 years without anything against him. There were no fewer than 965 Orders in Council affecting grocers, and for 35 years he had successfully steered through these 965 Orders in Council only to be held up through not putting his name on a paper wrapper. The police superintendent stated that defendant was a highly respectable tradesman, and that the proceedings were brought as a warning to others. The Justices dismissed the case on payment of costs.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg.-Comdr. P. L. Gibson to *Pembroke*, for R.N. Hospital, Chatham.

ROYAL NAVAL VOLUNTEER RESERVE.

Act. Comdr. R. P. Pim to *Excellent*, Surg.-Lts. A. R. Thomas to *Comus*, for training, and E. E. Henderson to *Vivid*, for R.N. Barracks, Devonport, for training.

Surg. Sub.-Lt. J. A. White promoted to Surg.-Lt.

Proby. Surg. Sub.-Lt. T. Colver to *Victory*, for R.N. Hospital, Haslar, for training.

J. K. Reid, Birkenhead, has been appointed Admiralty Surgeon and Agent for that district.

ROYAL ARMY MEDICAL CORPS.

Maj. N. Cantlie, M.C., half pay list, is restd. to the estabt., with precedence next below H. G. Winter, M.C.

Maj. H. H. Leeson, M.C., R.A.M.C., Res of Off., relinquishes his appt. under Art. 607 (b), Royal Warrant for Pay and Promotion, 1926, and resumes the rank of Lt.-Col.

Maj. (Qr.-Mr.) C. A. Figg, O.B.E., having attained the age for compulsory retirement, is placed on retd. pay.

TERRITORIAL ARMY.

Lt.-Col. (Bt.-Col.) F. Marsh (late R.A.M.C., T.F.), to be Hon. Col., R.A.M.C. Units, 48th (S. Midland) Div.

Lt. E. G. Oastler to be Capt.

W. H. D. Patterson and 2nd Lt. E. H. Brindle (late R. Scots) to be Lts.

ARMY DENTAL CORPS.

Lt. (on prob.) G. E. Nettleship is confirmed in his rank.

ROYAL AIR FORCE.

The undermentioned Flying Officers are granted permanent commissions in this rank: G. H. J. Williams, J. C. Neely J. Kemp.

Flying Officer J. M. Ritchie is promoted to the rank of Flight Lt.

Flying Officer A. C. Lysaght resigns his short service commission.

RESERVE OF AIR FORCE OFFICERS.

Flight Lt. J. D. Driberg is granted a commission in Class D.D.

Squadron Ldr. H. Harvey relinquishes his commission on completion of service and is permitted to retain his rank.

AUXILIARY AIR FORCE.

No. 601 County of London (Bomber) Squadron.—Flight Lt. J. D. Driberg resigns his commission on appoint*ment to the* Reserve of Air Force Officers.

Flight Lt. E. D. W. Reid is transferred from General Duties Branch.

INDIAN MEDICAL SERVICE.

Capts. D. P. McDonald, Amar Nath Sharma, and Naval Maneckji Pestonji Dotivala, M.C., to be Majs.

Temp. Lts. Karam Chand Virmani and Tolaram Bhojsing Pahlajani to be Temp. Capts.

Lt.-Col. J. K. S. Fleming retires.

Lts. E. G. Montgomery, G. F. Taylor, and Wajid Ali Khan to be Capts.

Lt. R. A. Haythornthwaite to be Capt. (prov.).

The undermentioned temp. officers are apptd. to permanent commns. as Lts.: Chandra Mani, Lakshman Dass, Prafulla Chandra Dutta, and Trilok Chand Puri.

Capts. to be Majs.: Kombar Ramaswamy Krishnaswami Iyenger, Madho Prasad, Girish Chandra Maitra, J. J. Rooney.

The following Capts. (prov.) are confirmed in their rank: Gurbaksh Singh Chawla, T. A. Malone, W. Scott, Bhagwant Singh Nat, V. A. Edge.

Lt.-Col. H. M. H. Melhuish, D.S.O. retires.

The *London Gazette* of Sept. 6th published under 14 paragraphs from the India Office the amended rules for the promotion and precedence of the Indian Medical Service contained in the Warrant of May 28th, 1918, and in such other Warrants granted since that date as are still in force.

COLONIAL MEDICAL SERVICES.

The following appointments are notified: R. E. Anderson, Medical Officer, Federated Malay States; Miss N. N. Lowther, Lady Medical Officer, Federated Malay States; L. E. Vine, Medical Officer, Federated Malay States; Miss C. D. Williams, Lady Medical Officer, Gold Coast; F. W. W. Fox, Medical Officer, Nigeria; F. Williams, Pathologist, Nigeria.

Appointments.

SCOTT, JOHN A., M.D. Liverp., D.P.H., has been appointed Medical Officer of Health for Shipley.

Vacancies.

For further information refer to the advertisement columns.

Albert Dock Hospital, Connaught-road E.—Surgeon. Also M.O. At rate of £110.

All Saints' Hospital for Genito-Urinary Diseases, Finchley-road, N.W.—Jun. H.S. Also Asst. H.S. At rate of £150 and £100 respectively.

Ashton-under-Lyne, District Infirmary.—H.S. At rate of £150.

Bangor, Carnarvonshire and Anglesey Infirmary.—H.S. £200.

Barrow-in-Furness County Borough.—Asst. M.O.H. and Asst. Tub. O. £600.

Birkenhead General Hospital.—Cas. S. £100.

Birmingham Ear and Throat Hospital.—Third H.S. At rate of £150.

Birmingham and Midland Ear and Throat Hospital.—Asst. Surg. O. £200.

Blackburn and East Lancashire Royal Infirmary.—Res. H.P. £150. Also 4th H.S. £130.

Bournemouth, Royal Victoria and West Hants Hospital.—Two H.S.'s. Each at rate of £120.

Bradford, Royal Eye and Ear Hospital.—Jun. H.S. £120.

Bristol City and County Mental Hospital.—2nd Asst. M.O. £500. Also 3rd Asst. M.O. £350.

Cape Town University.—Asst. Anatomist. £750.

Cardiff Royal Infirmary.—Gynæcological H.S. Also Ophthalmic H.S. At rate of £50 and £75 respectively.

Carlisle, Cumberland Infirmary.—H.P. £155.

Chelmsfield and Essex Hospital.—Res. M.O. At rate of £150.

Chichester Royal West Sussex Hospital.—Jun. H.S. £150.

Coventry City.—M.O.H. £1225.

Croydon General Hospital.—2nd Asst. for the Pathological and Bacteriological Laboratory. £3 10s. per week.

Cyprus, Pendayia Hospital.—Surgeon-Physician. £25 per month.

Dorchester, Dorset County Hospital.—H.S. At rate of £120.

Dreadnought Hospital, Greenwich.—H.P. and H.S. Each at rate of £110.

Dublin University, School of Physic, Trinity College.—Montgomery Lecturer in Ophthalmology. £150.

East Ham Memorial Hospital, Shrewsbury-road, E.—Res. M.O. At rate of £200.

East London Hospital for Children, &c., Shadwell, E.—Res. Cas. O. At rate of £125.

Evelina Hospital for Children, Southwark, S.E.—H.S. At rate of £120.

Freemasons Hospital and Nursing Home, 237, Fulham-road, Chelsea, S.W.—Res. M.O. At rate of £250.

Gloucester, Gloucestershire Royal Infirmary, &c.—Hon. S. to Ear, Nose and Throat Dept.

Great Yarmouth General Hospital.—Sen. H.S. £150.

Grimsby County Borough and Port of.—Part-time Clin. Tuberculosis O. and Assist. M.O.H. £750.

Guildford, Royal Surrey County Hospital.—H.S. £150.

Hampstead Parish of St. John, New End Hospital.—Jun. Res. Asst. M.O. At rate of £200.

Hospital for Sick Children, Great Ormond-street, W.C.—Asst. Path. and Research Fellow. £450. Also H.S. and H.P. Each at rate of £100.

Hull Royal Infirmary.—Asst. H.P. At rate of £130.

Indian Research Fund Association, Simla.—Bacteriologist. Also Research Worker. Each Rs.1500 per mensem.

Isleworth, West Middlesex Hospital.—Res. Asst. Med. Supt. and Asst. M.O. £450.

King's College Hospital, Denmark Hill, S.E.—Clinical Assistantships.

King's Lynn, West Norfolk and Lynn Hospital.—Sen. H.S. Also Jun. H.S. At rate of £150 and £100 respectively.

Lewisham Metropolitan Borough.—Asst. M.O.H. and Maternity and Child Welfare M.O. £650.

Liverpool, St. Paul's Hospital, Oldhall-street.—H.S. £120.

London Jewish Hospital, Stepney Green, E.—Hon. Asst. S. for Gynæcological Dept., Hon. Asst. Radiologist. Also Hon. M.O. for Actino-Therapeutic Dept.

London Lock Hospital, 91, Dean-street, W.—H.S. At rate of £200.

London Temperance Hospital, Hampstead-road, N.W.—Res. M.O. At rate of £175.

Manchester, Baguley Sanatorium.—Asst. M.O. £350.

Manchester Babies' Hospital, Burnage-lane, Levenshulme.—Jun. Res. M.O. At rate of £50.

Manchester, Salford Royal Hospital.—Two H S.'s. Also Cas. H.S. Each at rate of £125

Margate, Royal Sea Bathing Hospital.—H.S. At rate of £100.

Northampton, Northamptonshire County Council.—M.O.H. and School M.O. £1,100.

Norwich, Jenny Lind Hospital for Children.—Res. M.O. £120.

Norwich, Norfolk and Norwich Hospital.—H.S. £120.

Nottingham Children's Hospital.—Res. H.P. At rate of £150.

Nottingham General Hospital.—H.P. Also 2nd Cas O. Each at rate of £150.

Otago and Dunedin University Hospital, New Zealand.—Sen. Res. M.O. £500.

Port Said, British Hospital.—Res. A.M.O. £350.

Princess Louise Kensington Hospital for Children, North Kensington.—Hon. Radiologist.

Prince of Wales's General Hospital, Tottenham, N.—Sen. H.P. Sen. H.S., and Special H.S. Each at rate of £120. Also Jun. H.P., and Two Jun. H.S.'s. Each at rate of £90.

Rotherham Hospital.—H.S. £180.

Queen's Hospital for Children, Hackney-road, E.—H.P. Also Cas. O. Each at rate of £100.

Royal Chest Hospital, City-road, E.C.—Res. M.O. At rate of £150. Also Out-patient M.O. and H.P. Each at rate of £100.

Royal Dental Hospital of London, 32, Leicester-square, W.C.—Hon. Anæsthetist.

St. Leonards-on-Sea, Buchanan Hospital.—Jun. H.S. £125.

South London Hospital for Women, South Side, Clapham Common, S.W.—H.P. Also 3 H.S.'s. Each at rate of £50.

Swansea Hospital.—H.S. £150.

Swindon Corporation.—Asst. M.O.H. £600.

Talgarth, Breconshire, South Wales Sanatorium.—Sen. Asst. M.O. £350.

Torquay, Torbay Hospital.—H.S. £175.

Tunbridge Wells and Counties General Hospital.—H.S. £160.

Worcester General Hospital.—Jun. Res. M.O. £120.

The Chief Inspector of Factories announces a vacant appointment for a Certifying Factory Surgeon at Portland (Dorset).

Births, Marriages, and Deaths.

BIRTHS.

GILDING.—On Sept. 5th, the wife of H. P. Gilding, B.M., B.Ch.Oxf., of a daughter.

HORROCKS.—At a nursing home, Manchester, the wife of F. S. Horrocks, M.B., Ch.B. Manch., of Gravesend, of a daughter.

HURRELL.—On Sept. 6th, at the Penlea Nursing Home, Newcastle-upon-Tyne, to Dr. and Mrs. George Hurrell, 31, Dencholm, Monkseaton—a daughter.

TAUNTON.—On Sept. 3rd, at Campbell-road, Hanwell, W., the wife of R. E. M. Taunton, M.B., Ch.B. Edin., of a daughter.

MARRIAGES.

COOKE—COWIE.—On Sept. 5th, 1920, at the Parish Church, Banff, by the Rev. D. Findlay Clarke, B.D., Robert Victor Cooke, M.B., Ch.B. Bristol, F.R.C.S. Eng., eldest son of Mr. and Mrs. John Cooke, Berkeley, Gloucestershire, to Betty Cowie, M.D., B.S. Lond., M.R.C.P. Lond., elder daughter of Hugh Gordon Cowie, M.A., M.D., Banff, Scotland.

FARR—EMERY.—On Sept. 2nd, at Holy Trinity, Coombe Down, E. A. Farr, M.R.C.S. Eng., L.R.C.P. Lond., of Andover, to S. A. Emery, of Bath.

GREGORSON—HOWE.—On Sept. 4th, at All Saints', Horsford Parish Church, Norwich, Albert William Gregorson, M.D. Glasg., to Edith Evelyn Howe.

WILSON—SMITH.—On August 31st, at Tiviot Dale Chapel, Stockport, John Greenwood Wilson, M.D. Lond., M.R.C.P. Lond., younger son of the Rev. John Wilson, M.B.E., D.D., of Woolwich, to Wenda Margaret Hithersay, eldest daughter of Ernest J. Smith, M.A., LL.B., of Disley, Cheshire.

DEATHS.

AMBLER.—On Sept. 9th, at Ampthill, R. Ambler, Esq., F.R.C.S., L.R.C.P. & S. Ed., L.R.F.P.S. Glasg., aged 72, last surviving son of Dr. E. H. Ambler, of Hemel Hempstead.

CAIGER.—On Sept. 5th, suddenly in Scotland, Frederick Foord Caiger, M.D. Lond., F.R.C.P., late chief medical officer, Infectious Hospitals Service, Metropolitan Asylums Board, aged 69 years.

CRAIG.—On July 26th, at the Cottage Hospital, Fort Beaufort, Peter Latimer Craig, M.A., B.Sc., M.B., C.M. Glasg., D.P.H. Camb., of Balfour, Cape Province, S. Africa.

HARRIS.—On Sept. 6th, at Hartwood House, Chorley, Lancashire, James Alfred Harris, M.D. Lond.

LOCHHEAD.—On Sept. 2nd, at Desenzano, Italy, after a short illness, Mathew Lochhead, M.B., C.M. Glasg., B.Sc., of Snaxland, Clovelly, Devon.

SHARKEY.—On Sept. 6th, at Portland-place, London, Sir Seymour J. Sharkey, M.A., M.D. Oxf., F.R.C.P. Lond., consulting physician to St. Thomas's Hospital, aged 82 years.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

ENLARGEMENT OF DEAL HOSPITAL.—The Deal and Walmer War Memorial Hospital, which last year had a credit balance of over £1100, is to be enlarged by the erection of a nurses' home at the back, thus enabling the whole of the present building to be used as wards. The cost will be £10,000.

ST. BARTHOLOMEW'S HOSPITAL.—In his annual report, Lord Stanmore, the treasurer, states that the erection of the surgical ward block is making good progress and that the buildings should be ready for occupation by the beginning of next year. There will be five surgical units, each comprising a male and a female ward of 22 beds, with two small wards of one and two beds respectively attached to each section. Each unit has its own operating theatre, demonstration room, examination room, and offices. These buildings form part of the complete scheme of reconstruction. The Governors have approved a southern extension of Queen Mary's Home for the nurses, which will provide for 51 additional nurses. The in-patients last year numbered 9808 and cost £10 1s. 4d. each; the 94,803 new out-patients cost 11s. 1d. each. The income was £198,765 and the expenditure £201,774.

Medical News.

DEPARTMENT OF SCIENTIFIC AND INDUSTRIAL RESEARCH.—Lord Rayleigh, F.R.S., Sir Arthur Balfour, Sir William Bragg, F.R.S., and Sir James Walker, F.R.S., have been appointed members of the Advisory Council in succession to Sir Harold Carpenter, F.R.S., Mr. G. C. Clayton, Ph.D., Sir Richard Glazebrook, F.R.S., and Sir James Jeans, Sec. R.S., who have retired on completion of their terms of office.

Dr. Leonard Nicholas Robinson, O.B.E., President of the Egyptian Medical Commission in Paris, has been granted His Majesty's royal licence and authority to wear the Insignia of the Third Class of the Order of the Nile, conferred upon him by the King of Egypt, in recognition of valuable services rendered by him.

TORBAY HOSPITAL CONTRIBUTORY SCHEME.—At the end of the first four months' working of this scheme the membership had reached nearly 15,000.

PAIGNTON HOSPITAL.—An enlargement of this hospital was opened last week by Mrs. J. A. Watson. It consists of a new wing, containing a men's ward, a women's ward, and accommodation for paying patients. The work has cost £15,000.

ANCOATS HOSPITAL, MANCHESTER.—A course of post-graduate lectures and demonstrations will be given during the Michaelmas Term on Thursday afternoons at 4.15 P.M., commencing on Oct. 17th, when Dr. W. J. S. Reid will speak on Hæmorrhagic Diatheses. A notice of each lecture will be inserted in THE LANCET of the preceding week. All medical graduates and senior students are invited, and there is no fee for the course. In addition to this course a post-graduate day of clinical teaching will be given by the honorary staff every Thursday during the Lent Term as part of the post-graduate scheme of the University of Manchester.

ASSOCIATION OF SPECIAL LIBRARIES AND INFORMATION BUREAUX.—The programme of the sixth annual conference, to be held at Trinity College, Cambridge, from Sept. 20th–23rd, has been issued. Among the subjects to be considered are the Ideal Form of a Journal from the Librarian's Point of View, Duplication and Infringement of Copyright, Technical English, the Training of Special Librarians, the Indexing and Classifying of Individual Collections of Data, and International Organisation of Information Services. A dinner will be held on Sept. 20th, when Sir J. J. Thomson, F.R.S., president-elect of the Association, will give an address. Full particulars can be obtained by those interested from the Secretary, A.S.L.I.B., 26, Bedford-square, London, W.C.

OPTICAL CONGRESS.—A congress and trade exhibition is being held at the Northampton Polytechnic Institute, St. John-street, London, E.C., to commemorate the tercentenary of the granting of the Royal Charter to the spectacle makers of the City of London. The congress was opened on Sept. 10th by Sir Osborn Holmden, Master of the Worshipful Company of Spectacle Makers. He said that at the end of last century the Company had decided to institute an examination for the craft, and at the present time nearly 2500 opticians held the Company's diploma. It was the object of the Company and of other optical bodies to raise the code of ethical practice among opticians and to ensure that persons afflicted by disease and needing treatment should be referred to ophthalmic surgeons.

"THE MIDLAND HOMŒOPATHIC AND GENERAL HOSPITAL" is the new name of the institution formerly known as the Birmingham and Midland Homœopathic Hospital and Dispensary. The 50 beds are always full, and 710 in-patients were treated last year; there were 3745 out-patients and 982 operations. The finances show an annual loss. The average cost per in-patient per week was £3 2*s.* 10*d.*, as against £2 0*s.* 4*d.* in the previous year.

THE SHEFFIELD HOSPITALS.—The seventh annual report of the Sheffield Hospitals Council, which administers the penny-in-the-pound scheme, states that the total number of patients admitted to the four institutions last year was 16,433. Children, unemployed, and patients unable to pay towards their maintenance numbered 6051, and for these persons and the necessitous poor the Council expended £60,000. The casualties exceeded 40,000, an average of 134 per day; out-patients totalled just under 74,000. At the end of the year the waiting list contained 2087 names and the accumulated debt to the bankers exceeded £59,000,

Notes, Comments, and Abstracts.

MEDICAL EXAMINATION OF CANDIDATES FOR THE POLICE FORCE IN 1844.

THE standards of fitness for candidates for the most physically exacting of our national services were the subject of comment in our columns last week. We have received from Dr. A. P. Gibbons a copy of the instructions issued nearly a century ago, for the guidance of the surgeon to the police force of the City of London, on his duties when examining candidates for the Force, and it is interesting to compare the criteria of sturdy vigour then established with more modern ones. The document, dated 1844, reads as follows:—

Instructions for the Guidance of the Surgeon.

I. The leading object of the following instructions is to guard against the admission of candidates into the Force whose health of body or mind is unsound who have any suspected taint of disease or disability and who, at the period of Inspection, are incapable of undergoing fatigue. The Duties of the Force to be efficiently performed necessarily require that each Member should enjoy sound Bodily health, as well as a fair proportion of physical strength and an appearance likely to command obedience.

II. The Surgeon is from his knowledge of the Duties of the Members of the Force, presumed to be capable of forming a correct opinion of the health of Candidates their capacity for exertion and general efficiency. The external characters of a sound constitution and efficient limbs may be briefly stated, viz., a tolerably just proportion between the trunk and different Members of the Body a Countenance expressive of health with a lively eye—Skin firm and elastic—Lips red—Teeth in good condition—Voice strong—Chest capacious and well formed—Belly lank—Limbs muscular—Feet arched and of a moderate length—Hands rather large than small—The reverse of these marks of a good constitution and efficiency may be considered to indicate infirm health or inefficiency.

III. The question of fitness or unfitness of a candidate must in a great measure be determined by the discretion of the Surgeon for no rule can be formed of so definite a character as to dispense with the exercise of the deliberate reflection and judgment of a Medical Man.

IV. As policemen are liable to be exposed to frequent vicissitudes of weather and to undergo much fatigue Candidates should possess vigorous constitutions and great muscular capability; hence no Man ought to be approved for the Service whose health is unsound and who does not possess adequate strength for the duties which he may be called upon to perform.

V. The following enumeration of the more common causes for which Candidates should be rejected when any of them exist to such a degree as will immediately, or in all probability may at no very distant period impair a Man's efficiency, is intended as a general guide to the Surgeon in the performance of the duty of inspecting Candidates.

1. Feeble constitution, unsound health from whatever cause, indications of former disease, as Leech bites, traces of Blisters, thereby showing a liability to infirm health, nodes, glandular swellings, or other symptoms of Scrofula, &c.
2. Weak or disordered Intellect.
3. Chronic cutaneous affections, especially of the Scalp.
4. Severe injuries of the Bones of the Head.
5. Impaired vision from whatever cause, or Inflamatory affections of the Eyelids, immobility or irregularity of the Iris, Fistula Lachrymalis.
6. Deafness or copious discharge from the Ears.
7. Loss of many Teeth or the Teeth generally unsound.
8. Impediment of Speech.
9. Want of due capacity of the Chest and any other indication of a liability to pulmonic Disease.
10. Impaired or inadequate efficiency of one or both of the superior extremities on account of palsy, old fractures, especially of the Clavicle, Contraction of a Joint, Mutilation, Extenuation, Deformity, Ganglions, &c., &c.
11. Lateral and other Curvatures of the Spine.
12. Hernia or a tendency to that disability from preternatural enlargement of the abdominal ring.
13. A varicose state of the Veins of the Scrotum or Spermatic Cord, Sarcocele, Hydrocele, Hemorrhoids, Fistula in perineo.
14. Impaired or inadequate efficiency of one or both of the inferior extremities on account of Varicose Veins, old Fractures, Malformations (flat feet, &c.), Palsy or Lameness, Contraction, Mutilation, Extenuation, Enlargement, unequal length, Bunions overlying or supernumerary Toes, Ganglions, &c., &c.

15. Ulcers or unsound cicatrices of Ulcers likely to break out afresh.
16. Diseases whether Acute or Chronic for which Medical treatment is required.

VI. Every Candidate is to be undressed before Inspection and it is directed that the Examination shall be conducted agreeably to the following Routine, by which means blemishes are not likely to escape detection.

VII. Upon entering the Inspection Room the Candidate is to walk a few times pretty smartly across the Apartment for the purpose of showing that he has a perfect use of his lower extremities. He is then to be halted and set up in the position of a Soldier under Arms with the Knees about an inch apart and examined both in front and rear from head to foot. Should no material defect be discovered during this Survey the Examination may go on. The Candidate is then to perform the following Evolutions:—to extend the arms at right angles with the trunk of the Body, then to touch the Shoulders with the fingers, next to place the backs of the hands together above the head in this position let him cough, while at the same time the Surgeon's hand is to be applied to the rings of the external oblique muscles. Let the Surgeon examine the Spermatic Cord and Testes, then pass his hands over the Bones of the Legs. The Candidate is next to be made to stand upon one foot, and move the ankle joint of each extremity alternately; when any doubt is entertained respecting the efficiency of this joint or any part of an inferior extremity he should be made to test his strength by hopping upon the suspected Limb for a short period, and the size and aspect of the corresponding joint or part of the opposite Limb should also be accurately compared. He is next to kneel on one knee, then on the other and subsequently on both knees. Let him then stoop forwards and place his hands on the Ground and while in this position it ought to be ascertained whether he be affected with Hemorrhoids. He is then to extend the superior extremities forward for the purpose of having his arms and hands examined, and with this intention he is to perform flexion and extension of the fingers and to rotate the forearm. The Head is next to be examined, including the scalp, ears, eyes, nose, mouth; the Surgeon is then to ascertain that he possesses the function of hearing, and the faculty of distinct enunciation. In regard to the mental faculties the Surgeon should invariably ask a Candidate a few short questions as what occupation he had previously followed, &c., &c., or adopt any other means which he may deem necessary to ascertain the condition of the intellect.

VIII. When a Candidate is approved the attestation is to be filled up and signed by the Surgeon.

IX. The Book required to be kept in regard to this Branch of the duty of the Surgeon is, a register of Candidates which is to be ruled so as to contain the following heads: (a) Date of examination. (b) Name of each Candidate. (c) Age. (d) Country of Birth (as England, Ireland or Scotland). (e) Previous occupation or Station in life. (f) Remarks and Observations.

Causes of Rejection.—Unsound Health. Weak Intellect. Traces of Scrofula. Muscular Tenuity. Chronic Cutaneous affections. Specks on the Cornea; Cataract. Deafness. Loss of many Teeth. Defective condition of the superior extremities in consequence of old fractures, contractions, &c. Deformed Spine. Hernia Inguinal on either side. Laxity of the ring of the external Oblique Muscles on either side. Varicose Veins, left or right Spermatic Cord. Disease of the left Testicle. Disease of the right Testicle. Hydrocele of either testicle. Defective condition of the Inferior Extremities in consequence of old fractures. Malformation. Varicose Veins of either legs. Ulcers, Wounds or Cicatrices of legs.

Modern Practice.

We understand that at the present time the question of fitness or otherwise of candidates for the City of London Police is largely left to the examining surgeon. Each candidate fills up a form on which he sets out his name, age, vaccination history, notes of illnesses for which medical attention has been required, and reports any history of hæmoptysis, fits, rheumatic fever, or discharge from the ears. He is asked on the same form whether he or any near relative has been afflicted with consumption, epilepsy, insanity, or nervous debility, whether he has ever been ruptured, and what, if his parents are not living, was the cause of their death. The surgeon then examines the candidates stripped, so that varicose veins, hernia, and deformities can be easily detected. His sight and hearing must be good and his organs sound; he should be six feet or more in height, have a mean chest measurement of 36 in., and weigh 11 stone or more when stripped. The use of stethoscope has, of course, made unnecessary such full ctions as were offered to the surgeon of 1844, and has a better estimate of the function of the respiratory systems to be made, but it is remarkable have altered since the early instruc- ed.

SOME ASPECTS OF HOSPITAL PLANNING.

In an address with this title, recently delivered before the Rotary Club at Welwyn Garden City, Mr. A. W. Kenyon, F.R.I.B.A., spoke of the choice of site for a general hospital, more especially as it might apply to a garden city. One of the most important factors was the selection of a really beautiful site, a point which often appeared to be overlooked, leaving architects to face the problem of fitting a hospital on to a difficult and unsuitable site. There were many reasons why this was so. The land might be given by a philanthropist who did not fully appreciate the requirements of future development, or the land might not be available in the particular district in which the hospital was required. In Welwyn, however, it should be quite possible to select an ideal site. It was essential in the first instance that the site should be large enough for future as well as present demands. There should be a broad frontage facing south and the ground fall gently towards the south, with access roads from the north and east, where there should be the shelter of a belt of trees. The amount of land required would depend on the type and size of the hospital to be erected. The modern tendency was to secure smaller hospitals in towns where noise is daily on the increase, and to make them tributary to larger hospitals in the country where fresh air can be obtained and plenty of space secured for gardens for convalescents. This ideal, he thought, should appeal to places like Welwyn which were making efforts to bring works and the workers from congested and noisy towns into the better environment of the country. The hospital of the future was going to be a very efficient building, which would provide for: (a) general patients who would come under the voluntary system; (b) paying patients who could only afford to pay a contribution towards the services rendered to them; (c) private paying patients who would be able to pay adequately for these services; (d) smaller wards; (e) special blocks, all of which were tending to increase the size of hospitals. If Welwyn was going to provide a hospital suitable for the county and so to relieve the more thickly populated towns, there was hardly any limit to the ultimate number of beds required. Having arrived at the probable number of beds ultimately needed, the hospital should be planned for the full accommodation, even if a small portion only was to be built. It was extremely difficult to add to an existing building if the future extension had not been thought out. There was the psychological effect to bear in mind, for donors would often contribute to some special department or would contribute towards finishing off a certain portion of the building. In new towns like Welwyn, run on idealistic principles, it should certainly be possible to plan a new hospital rather than adapt an existing building. To do the latter would be to find that when everything possible had been done, it was more than likely to prove a makeshift, uneconomical in planning, difficult to administer, and expensive to run.

PAINFUL FIBROSITIC NODULES.

To the Editor of THE LANCET.

SIR,—I offer the following suggestions for treatment. (1) Injections of fibrolysin; (2) paint painful nodules with analgit (the Analgit Co., 102, Wilmslow-road, Didsbury, Manchester); (3) a sodium iodide and sodium salicylate mixture; (4) soneryl grs. ii. at bedtime with a hot drink, to ensure sleep till other remedies get to work.

I am, Sir, yours faithfully,
C. G. S. BARONSFEATHER, M.D.

Bournemouth West, Sept. 6th, 1929.

A COURTEOUS ACT.

We are in a position to supply the information desired by the Leicester Health Committee on the whereabouts of Dr. W. B. Castle, who earned the gratitude of the Committee by his services to a fellow passenger on the Ostend boat. Dr. Castle sailed on Sept. 7th for Boston, where he holds an appointment at the City Hospital, to resume the experimental work on the association of achlorhydria with pernicious anæmia which he reported to the Section of Medicine of the Royal Society of Medicine on June 11th. Dr. Castle's courtesy in escorting a woman whose labour had begun prematurely to her home in Leicester, and in attending her until he could procure suitable medical and nursing attention, was especially noteworthy since the incident curtailed his final visit to London before he sailed for America.

X. Y.—We understand that keraphen (or tetraiodophthalophenon), a preparation given by the mouth as a preliminary to cholecystography (see THE LANCET, August 24th, p. 400), may be obtained from Mr. James Picker, 686, Lexington-avenue, New York.

WE are informed that Prunol Products, Ltd. is continuing to place on the market the proprietary remedy for constipation and kindred ills known as prunol.

Lettsomian Lectures

ON THE

RELATIONSHIP OF DERMATOLOGY TO OTHER BRANCHES OF MEDICINE.

Delivered before the Medical Society of London

BY H. W. BARBER, M.B. CAMB., F.R.C.P. LOND.,
PHYSICIAN IN CHARGE OF THE SKIN DEPARTMENT, GUY'S HOSPITAL.

LECTURE III.*

IN my first lecture I emphasised the close relationship that exists between the skin and the endocrine-autonomic system, and indicated how the latter is to some extent dependent for its normal functioning on the physical stimuli—e.g., light and cool air—that the natural environment of the skin should provide. This relationship is evident again when one studies the conditions which I propose to consider in this lecture, conditions that are *symptoms* rather than distinct diseases. They come within the province of nearly every medical and surgical specialist, as well as of the pathologist, bacteriologist, and biochemist, but they concern no one more intimately than the dermatologists, who, I think I may say, have done much to elucidate their exact pathogenesis.

For the purposes of this lecture I shall divide those conditions or symptoms into two groups:—

Group 1 comprises those that Freeman[1] has labelled the toxic idiopathies.

Group 2 is a triad of cutaneous disorders which are closely related both to each other and to certain maladies that concern the general physician. They are alopecia areata, vitiligo or leucomelanoderma, and scleroderma.

The conditions included in these two groups have this in common, that they are associated with manifest disturbances of the vegetative nervous system and certain endocrine glands. Before considering them in detail, I would insist on one point—namely, the regrettable tendency that still exists of referring to them as if they were *diseases* sui generis, whereas they are merely symptoms, each, it is true, with its own mechanism of production, but of widely different causation in different cases. It is absurd, for example, to talk of a "cure" for asthma or of urticaria, or, for that matter, of alopecia areata and scleroderma; one might with equal justification speak of a "cure" for itching or diarrhœa. Conversely, it is to my mind just as misleading to inform the victims of, say, asthma that there is no certain cure for their disability, for such a statement merely propagates the erroneous idea in the minds of the lay public that asthma is a definite disease of specific causation.

GROUP 1.

The Toxic Idiopathies.

The following list includes at any rate most of the recognised toxic idiopathies:—

Cutaneous.—Urticaria; true infantile eczema; certain forms of eczema occurring after infancy; certain forms of pruritus; prurigo of the Besnier type; prurigo of the Hebra type; prurigo of the simple type; prurigo nodularis; urticaria papulosa (lichen urticatus, strophulus); light-sensitisation of the adult type; dermatitis herpetiformis (probably).

Subcutaneous.—Angeioneurotic œdema.

Respiratory.—Paroxysmal rhinitis, of which hay-fever is one of the commonest examples; asthma.

Gastro-intestinal.—Certain forms of vomiting and diarrhœa; cyclical vomiting.

Nervous.—Migraine; epilepsy (probably).

Articular.—Paroxysmal hydrarthrosis.

I employ the term "toxic idiopathies," coined by Freeman, to describe the various symptoms included in this group, because it conveniently indicates their toxic origin, and implies what we call "idiosyncrasy," which is apparently a striking factor predisposing to their occurrence. By idiosyncrasy in this connexion we mean that certain persons have an inborn tendency to develop hypersensitiveness towards one or more foreign substances, such as animal or plant emanations, foodstuffs, drugs, &c. Thus only a small proportion of persons develop the hypersensitiveness to certain pollens that betrays itself by the paroxysmal rhinitis we call hay-fever, but many of them are also sensitive to other substances—e.g., foods, drugs, or animal emanations—which may produce different symptoms such as asthma, urticaria, eczema, or diarrhœa. This individual tendency to become sensitised—or idiosyncrasy—is, as is well known, a hereditary and familial trait, and Coca,[2] emphasising the influence of heredity, has suggested the term "atopy," in order to distinguish the basic factor underlying the genesis of the toxic idiopathies from true allergy and anaphylaxis.

Nevertheless, although every clinician recognises this hereditary and familial factor, as Bloch[3] points out, idiosyncrasy is a relative term, and its incidence varies according to the substance or idiosyncrasiogen towards which sensitiveness may develop. According to Coca and others over 60 per cent. of persons are or become sensitive to poison-ivy; Bloch states that 80 per cent. of all adults are sensitive to the round-worm ascaris, and Ancona[4] that all workers with grain, infested with the acarus, *Pediculoides ventricosus*—the cause of so-called grain-itch—eventually develop asthma. Moreover, according to Schittenhelm and Stockinger, all those who constantly handle salts of nickel sooner or later suffer from nickel dermatitis. We thus see the liability to become sensitised by repeated or constant contact with *certain* substances is found in a much greater proportion of persons than can be attributed to individual idiosyncrasy.

Cranston Low[5] succeeded in sensitising his own skin and that of his brother to *Primula obconica*, but failed with six other persons. In Low's case there is a history of asthma on the maternal side, and his mother suffered at one time from primula dermatitis, but in the unsuccessful cases also two had a family history of asthma, and the mother of another had had primula dermatitis.

Only a relative small proportion of those who handle *P. obconica* become sensitised, and there is often a familial idiosyncrasy towards it. Bloch, however, prepared a *concentrated extract* of the plant, and painted with it a small area of the skin of normal persons, including himself. *In every case* he thus succeeded in producing *sensitisation of the whole skin, so that subsequent contact with the plant* was followed by an acute eczematous dermatitis. As Bloch points out, the importance of this experiment lies in the fact that, by merely concentrating the antigen or idiosyncrasiogen, what is usually regarded as an idiosyncrasy—viz., primula sensitiveness—was transformed into a typical allergy. The experiment is, in fact, exactly comparable to the allergy produced by inoculating tubercle bacilli or certain ringworm fungi, as described in my second lecture. A primary focus was produced at the site of application of the primula extract, from which general sensitisation of the whole skin resulted. Moreover, Bloch was able to produce *focal reactions* in areas of skin to which the extract had previously been applied, but which had healed, on reapplication to other areas.

I think these observations show that the toxic idiopathies, although certainly often familial and hereditary, may, nevertheless, be regarded as allergic in nature. There is a type of person whose life-history may well be said to be one damned idiopathy after another. Often an ichthyotic, his troubles begin with infantile eczema; at about two years of age this may merge into the well-defined variety of prurigo known as the prurigo of Besnier; with this may appear asthmatic symptoms, and sooner or later attacks of urticaria, either of the papular or adult type, or of angeioneurotic œdema develop. Paroxysmal rhinitis, due to pollen, animal emanations, or other antigens, may follow, and acute attacks of eczema, caused sometimes by the skin having become sensitised to plants or chemical irritants, or there may be periodical attacks of vomiting and diarrhœa. Typical migraine may occur in childhood, or succeed some or all of these symptoms in later life.

---

* Lectures I. and II. appeared in THE LANCET of August 24th and Sept. 7th respectively.

Such extreme cases are relatively uncommon. It is in them that the familial and hereditary factor is usually most evident, and, although one particular symptom may be traced through several generations —and angeioneurotic œdema is a notorious example of this,—more often the affected members of the same family manifest different symptoms. Moreover, there is every gradation between these rare cases of hypersensitiveness to various antigens, with multiple symptoms of such hypersensitiveness, and the much more numerous cases of idiosyncrasy to one substance only, in which the familial tendency is lacking or uncertain. I always regard myself as practically normal in this respect, and, as far as I know, I have but one such idiosyncrasy—namely, to the human flea—which is not shared by any other members of my family. When I was an extern I was so badly flea-bitten that I became definitely ill with symptoms not unlike those of mild serum sickness. The only similar idiosyncrasy that I have been able to trace in my family is that my maternal grandmother was extremely sensitive to strawberries, but to nothing else.

It is likely, therefore, as Bloch's experiments suggest, that we are all at any rate potentially sensitisable, but that certain persons are much more so than others, and in them the tendency is commonly inherited and transmissible to their children. Probably, as will be seen later, what is inherited is a disordered balance or "make-up" of the endocrine-autonomic system on which this tendency depends; this view is strengthened by the fact that a perfectly normal person, with no inherited predisposition, may, under the stress of an acute or chronic infection, or of a severe emotional shock, develop symptoms of such an endocrine autonomic disturbance, and simultaneously, for the first time in his life, one or more of the toxic idiopathies. I have, for example, seen chronic urticaria, angeioneurotic œdema, the prurigo of Besnier, or asthma, develop suddenly in adults hitherto apparently normal in every way, after acute infection or psychical shock, there being at the same time signs and symptoms of thyroid-adrenal-sympathetic exhaustion.

If, then, we admit that idiosyncrasy is but a relative term, and that we are probably all at least potentially sensitisable, there is no reason to discriminate between the atopy of Coca and allergy, and, personally, I think that the toxic idiopathies may justifiably be considered as allergic reactions, and the cutaneous manifestations of the group be compared, as regards their mechanism of production, to the recognised allergic eruptions such as the tuberculides and trichophytides. With regard to *anaphylaxis*, I agree with Bloch that "the entire process has all the earmarks which dermatologists have learned to regard as characteristic of allergic reactions," and that "only on historical grounds can one understand that some still insist on giving it a special classification, instead of including it under allergy, and stress as particularly characteristic and typical the anaphylactic symptoms of the guinea-pig."

It may be as well at this point to define what we mean by allergy, and I think one of the most comprehensive definitions is that of Bloch:—

> "Allergy is that state which has as its basis the property of certain groups of cells (organs) of the living organism to react in a specific manner when brought in contact with a substance, which is, as far as is known, foreign to the organ or cells; the characteristic of this specific pathologic process lies in the fact that it is caused by the reaction of this exogenous substance with its specific cellular fixed antibody. The basis and the essence of allergy is the ability of the living cell to react with the production of specific antibodies to the stimulus of foreign substances, which are, therefore, called antigens, as well as the fact that the contact of the antigen with its specific cellular fixed antibody causes a disturbance of cellular life, which usually results in an inflammatory reaction."

He then goes on to say:—

> "It is clear that an organism which possesses or has acquired (by previous contact) such specific antibodies will react to the application of the specific antigen differently from an organism which does not possess such antibodies (allergy = different reaction).
>
> "From this definition other qualities characteristic of the allergic process can be logically deduced. The type and course of the allergic reaction are independent of the nature of the antigen, but vary according to the localisation of the antibody, that is, according to which organ reacts to the antigen. The effect which a substance acting as antigen—namely, through reaction with its antibody, has on the organism is different from the simple pharmacological effect which the same substance has on an organism which does not have any antibodies."

For example, in the case of drugs, such as quinine or iodine, a pharmacological dose, which would be tolerated by a normal subject, would produce violent symptoms in a sensitised person.

In allergy not only are the tissue cells sensitised, but substances—"antibodies," to give them a non-committal term—may be present in the blood, and on them the possibility of active and passive immunisation and of desensitisation depends. Moreover, they enable us in certain cases to determine the substance to which a person is sensitised by means of the Prausnitz-Küstner reaction which has proved so invaluable in the study of allergy. It was employed by A. and M. Walzer[6] in their experimental studies on urticaria, and by it has been established a fact of great importance—namely, that true antigens are not necessarily proteins; in fact, it is probable that in all cases the actual specific antigenic bodies are non-protein substances of relatively simple chemical composition. This has been proved, for example, in pollen hypersensitiveness by Coca and W. Jadassohn, and in sensitiveness to various foods by the latter observer.

Thus in a child with egg-sensitiveness, mentioned by Bloch, a reaction could be produced on the skin of the child as well as on that of a person passively sensitised by the Prausnitz-Küstner method, not only with egg protein, but also with a protein-free dialysate of egg, and W. Jadassohn showed that the actual antigen of the ascaris worm, which provokes violent asthma or urticaria or dermatitis in sensitised persons, is not destroyed by heat and is dialysable: it is therefore not a protein. Moreover, Bloch and Karrer succeeded in preparing from primula plants a pure crystalline substance, with the formula $C_{14}H_{18}O_3$, which, in a quantity of only 0·02 mg., produced a widespread eczematous dermatitis in a sensitised person, characteristic of primula dermatitis.

Now in the various conditions we term the toxic idiopathies we meet with some cases—for example, urticaria from some definite food substance or hay-fever, in which there is specific sensitiveness to one or other pollen,—that are, so to speak, constants. The person has a definite idiosyncrasy, his skin gives a positive reaction to the specific antigen, and his serum will passively sensitise a normal person. The whole phenomenon can be reduced to a relatively simple physiological experiment. But in many cases no such specific sensitiveness can be determined.

Let us take urticaria as an example. We know from the researches of Lewis[7] and his co-workers that the urticarial wheal is provoked by the liberation of a histamine-like substance or histamine itself in the skin, which produces a primary local dilatation of the minute vessels, a widespread dilatation of the neighbouring strong arterioles brought about entirely through a local nervous reflex, and locally increased permeability of the vessel walls. This response may be evoked in certain persons merely by stroking the skin (dermographism); in other cases by the contact of an antigen with sensitised skin cells. It represents a local response to injury, and is presumably a defensive mechanism. But how are we to explain the so-called "psychogenic" urticaria, which certainly occurs? For example, a patient consulted me for recurring attacks of genuine urticaria and angeioneurotic œdema, which occurred only when he was confronted with an important business appointment, or the prospect of meeting strangers socially. The question of sensitisation can hardly arise here. Are we to suppose that in emotion or anxiety states there may occur a liberation of histamine, such as Lewis has tentatively suggested may be the cause of blushing? In any case, in patients of this type it would seem that there is adrenal-sympathetic insufficiency with relative predominance of the parasympathetic, and that in practically all the toxic idiopathies the anxiety state alone may provoke the paroxysms.

Vagotonia.

Since Eppinger and Hess[8] in 1910 first formulated their conception of vagotonia with its converse sympathicotonia, a great deal of argument for and against their thesis has taken place. The whole question is reviewed in Guillaume's[9] book "Vagotonies, Sympathicotonies, Neurotonies." That one cannot in actual practice sharply divide the vegetative nervous system into its parasympathetic and sympathetic portions is certain. Clinically, however, one does meet with persons in whom there is clearly a disturbance of the normal balance between these two portions of the autonomic system, as well as of the endocrine glands with which they are functionally so closely connected. To dismiss the whole idea as a wild theory, as some would do, is childish, since it is confirmed by pharmacological and other tests.

Persons belonging to Czerny's exudative diathesis—i.e., those manifesting the various toxic idiopathies—correspond more or less to the vagotonic type described by Eppinger and Hess, in which parasympathetic action tends to override that of the sympathetic. Bolten[10] considers that in them there is "a congenital insufficiency of the sympathetic system and of the endocrine glands with accelerator action."

In support of this view is the fact that the various acute manifestations of the exudative or allergic state (like those of anaphylactic or peptone shock) are relieved by adrenalin, and the tendency to their occurrence often lessened by the administration of thyroid, both of which, of course, stimulate the sympathetic; conversely they are aggravated by pilocarpine, which, on the whole, stimulates the parasympathetic.

On the other hand, it is but just to point out that the sweat glands are innervated by the sympathetic, yet pilocarpine, an exciter of the parasympathetic, provokes sweating, and atropine, which paralyses the parasympathetic, arrests it. Moreover, with the approach of death, at which time there is hyposympathicotonia and hypervagotonia, profuse perspiration occurs.

Whether or not, however, one accepts the conception of vagotonia, sympathicotonia, and of Guillaume's neurotonia, which is a sort of mixture of the two, there is no question that in the genesis of the different symptoms of the sensitised or allergic state the endocrine-autonomic system is intimately involved, just as it is in experimental anaphylaxis.

Factors Predisposing to the Manifestations of the Sensitised State or Toxic Idiopathies.

This relationship of the toxic idiopathies to the endocrine-autonomic system is clearly seen if one analyses the known factors predisposing to their occurrence. The principal ones are:—

(1) *Sensitisation to foreign substances*, whereby contact of the antigen with the sensitised tissues results in a train of phenomena, similar to those met with in experimental anaphylaxis, which, like the allergic reactions considered in my last lecture, are doubtless defensive in nature, and are associated with manifest disturbance of the vegetative nervous system. Drury[11] considers that the toxic idiopathies are essentially conservative, self-repairing mechanisms under parasympathetic control. At any rate, as I have said, they are on the whole accompanied by depression of the adrenal-sympathetic action with consequent predominance of the parasympathetic.

(2) *Peripheral irritation.*—This factor, the presence of a so-called reflex source of irritation, may be one of great importance, and is often forgotten. In asthma it is, of course, recognised that a nasal abnormality may be a provoking cause of the attacks by setting up a trigemino-vagal reflex; this is explained by Brodie and Dixon's classical experiments. Similarly, an overloaded stomach, or exposure to strong sunlight may excite the asthmatic paroxysm. The well-known experiments of Donaldson[12] on rectal distension, referred to in my first lecture, are of interest in this connexion. Many of the symptoms produced by an overloaded rectum are clearly the result, not of so-called intestinal toxæmia, but of reflex irritation of the autonomic nervous system, and are promptly relieved when the rectum is emptied. Guillaume[13] records a case of a soldier with various symptoms of the vagotonic state, including migraine-like headaches. He was found to have a small piece of shrapnel embedded in the left orbit, removal of which caused the entire disappearance of all his symptoms. Eye-strain, a painful tooth, and a misplaced uterus are other examples of peripheral sources of irritation that may provoke symptoms of sympathetic disturbance out of all proportion to their apparently trivial nature.

(3) *Psychical stimuli.*—I need not enlarge upon the influence of emotion, worry, and shock in precipitating or aggravating the symptoms of the allergic state. The work of Cannon, Crile, and others on the psychical factor in disturbances of the thyroid-adrenal-sympathetic system is well known, and has been admirably reviewed by Langdon Brown[14] in his Croonian Lectures on the Sympathetic Nervous System.

These three factors have been utilised by Hurst[15] and by Langdon Brown[14] to express asthma in a formula. The former has defined asthma as due to an irritable condition of the bronchomotor portion of the vagus nucleus, which causes it to react unduly to psychical or peripheral stimuli, or to foreign proteins in the circulating blood; under one or other of these stimuli there result bronchial spasm, and, as Langdon Brown suggests, vasomotor turgescence of the bronchial mucous membrane.

In toxic idiopathies other than asthma the same three factors may be operative, and this accounts for the fact that those who suffer from them fall, as Freeman[17] points out, into the hands of different specialists in turn—for example, the immunologist, the rhinologist, the dermatologist, the neurologist, the psychologist, the gastro-enterologist, and so on. Each has his own point of view, his own line of treatment. These patients, more than any others, provide the handle of accusation against specialism, and at the same time demand of their consultants a range of knowledge wider, I am afraid, than they usually obtain.

(4) There is yet a fourth factor which may, I think, when still further investigated elucidate much that is obscure—namely, the metabolic factor. Oriel,[18] working in my clinic, has shown that certain definite biochemical changes occur in the blood and urine before, during, and after the paroxysms or crises of allergic manifestations. It would appear that in true anaphylactic shock, in serum sickness, in the shock following extensive burns, and in the toxic idiopathies, such as asthma, hay-fever, urticaria, angeioneurotic œdema, migraine, cyclical vomiting, infantile eczema, and certain forms of prurigo, what may be called the biochemical formula is much the same. In the acute crises—e.g., an attack of urticaria, angeioneurotic œdema, migraine, or asthma—there is a definite cycle of changes in the blood and urine corresponding to the preparoxysmal, paroxysmal, and post-paroxysmal periods, and in chronic cases, such as in the prurigos or persistent urticarias, this cycle is repeated, the biochemical findings varying according to the exacerbations or remissions of active manifestations.

These investigations are being pursued both in patients and by animal experiments with promising results, but in the present state of our knowledge the difficulty of evaluating the influence of the metabolic factor is to decide to what extent the biochemical changes found are *the result* of the allergic reaction, and to what extent a metabolic error predisposes to their occurrence.

James Adam,[19] and following him, Haseltine,[20] La Forge[21] and others, have emphasised what they term the toxic factor in asthma, and have shown clearly that many chronic asthmatics may be entirely relieved of their symptoms after an initial treatment of detoxication by means of purgation and the promotion of diuresis and diaphoresis, followed by suitable dietetic rules and insistence on regular outdoor exercise. The same is true in the case of other idiopathies, such as urticaria, angeioneurotic œdema, and the prurigo of Besnier, which is so often accompanied by asthma. Moreover, even in cases of such specific sensitiveness as hay-fever, treatment along these lines may bring about a cessation of the attacks, in spite of exposure to the particular pollen to which the patient is susceptible.

The truth of this contention of Adam and his followers is beyond all question, and may be summed up by saying that, even in patients hypersensitive to a known specific antigen, freedom from active manifestations of such hypersensitiveness can, at any rate in some cases, be obtained by putting the patient under conditions ideal for the development of physical fitness, in spite of his being still exposed to the antigen to which he is sensitised. This is illustrated perhaps most strikingly in patients who are the allergics par excellence—namely, those belonging to the ichthyosis-asthma-hay fever-eczema-prurigo-urticaria syndrome, in whom there is hypersensitiveness to several antigens and multiple symptoms of allergy. If such a person live a completely out-of-door life in suitable surroundings with adequate exercise, combined with judicious heliotherapy, his symptoms disappear as soon as he attains a certain degree of physical fitness; his whole appearance is transformed, he may eat foods with impunity which formerly provoked one or more of his symptoms, and he can handle animals without risk, contact with which previously gave him asthma or attacks of paroxysmal rhinitis. In some cases, as is well known, the mere removal of such a patient from his home surroundings to hospital is sufficient to cause his symptoms to disappear, and, in spite of deliberately exposing him to antigens to which he is sensitised, it may be impossible to make them reappear. On the other hand, a return to his home and his former mode of life, or an emotional upset, may at once cause him to revert to his *status quo ante*. I do not for a moment believe that this effect of a change of surroundings is always due, as some would have us believe, to the patient being sensitised to antigens, such as moulds, dusts, and so on, present in his home; it may be true in a few cases, but in the majority it is not so. In some no doubt the effect is chiefly psychical, in others it is due to the restoration of the metabolic functions to normal.

Unquestionably the treatment par excellence for these allergic patients is, as I have said, to put them under conditions which are most favourable for the proper working of their purely animal functions. In the artificial environment of urban civilisation they are unable to adapt themselves to their surroundings either psychically or physically, and this maladaptation would seem to be partly due, as Bolten suggests, to an inborn insufficiency or hypotonia of the sympathetic and of the accelerator endocrine glands, chiefly the adrenals and thyroid; both their metabolism and their endocrine-autonomic balance is disturbed.

As regards metabolism, the biochemical investigations referred to suggest that it is in the detoxicating functions of the liver that the clue to the problem lies; it would seem, in fact, that this is true both with substances reaching the liver viâ the alimentary tract, and with those introduced parenterally. For example, in the case of metallic drugs such as the arsenical, bismuth, or gold compounds, we know that tolerance of them is largely a function of the liver, and that intolerance may be sometimes prevented by administering glucose in sufficient quantity to ensure an adequate supply for glycogen formation which, as Roger[22] insists, is essential for the antitoxic and detoxicating hepatic functions. I think that the liver may be regarded as the first line of defence, and, when this breaks down, I believe the skin takes on a vicarious protective function, as represented by the various cutaneous manifestations of allergy.

GROUP 2.

Alopecia Areata, Vitiligo, Scleroderma.

These three conditions form a closely-linked triad, since they not only frequently occur together, particularly alopecia areata and vitiligo, but because all three are often met with in association with diseases of the endocrine-sympathetic system—for example, Graves's disease. The literature concerning them is enormous, but all that need now be said is that the sum total of the clinical and experimental observations published concerning them leads one inevitably to the conclusion that they are all due to involvement of the autonomic nervous system and the associated ductless glands. Nevertheless, the exact mechanism of their production is entirely obscure, and, when one attempts to formulate theories, one is met at once with apparently contradictory facts. For example, scleroderma, as the late Dr. Castle[23] pointed out in his exhaustive review of its literature, occurs so frequently in association with thyroid disorders that there must be a relationship between the two, yet it is found both in Graves's disease and in myxœdema. Dittisheim[24] observed scleroderma in eight cases of Graves's disease out of seventeen, yet the peripheral and generalised form—sclerodactyly—is usually accompanied by symptoms of Raynaud's disease, acroasphyxia, and hypothyroidism. I shall content myself by comparing the three conditions as regards certain features they possess in common, and then briefly deal with each in turn, and record some personal observations upon a few cases.

(1) *All three may occur in a localised and in a generalised form.*—Thus in the majority of cases of *alopecia areata* one or a few asymmetrical patches are found on the scalp or beard region, but in others the loss of hair may become generalised and involve the entire body. *Vitiligo*, though usually extensive and bilaterally symmetrical, may be localised to one area. *Scleroderma*, like alopecia areata, commonly occurs in patches—*morphœa*. Much rarer is the diffuse form, but the pathological changes would seem to be essentially the same, and the two forms may be met with simultaneously or at different periods in the same patient.

(2) *All three may occur in the so-called "band" form.*—Thus *alopecia areata* may rarely be seen to follow more or less the course of the supraorbital nerve, and Sutton[25] has seen it thus succeed an attack of supra-orbital herpes zoster. *Vitiligo* and more often *scleroderma* may also have this "band" distribution. Queyrat and Leri,[26] and Leri and Lamy,[27] have described cases in which both vitiligo and scleroderma were present, followed a zoniform or pseudo-root distribution, and were associated with spina bifida. Hutchinson[28] long ago described cases of scleroderma affecting the distribution of the fifth nerve, and compared it to herpes zoster. Anderson[29] reported a case of scleroderma involving the whole distribution of the right fifth nerve. Alterations were observed not only in the skin, but also in the mucous membranes supplied by the nerve, including the conjunctiva. Moreover, the hair fell out on the same side as high as the middle of the vertex. Sequeira[30] has recorded two cases of scleroderma corresponding in distribution to the first and second divisions of the fifth nerve, and O'Donovan[31] one in which the first and third were affected. Castle also described one in which the first and second divisions were involved. Presumably in these cases the changes in the skin are due to involvement of certain postganglionic sympathetic fibres coming from the superior cervical ganglion, and reaching the skin and mucous membranes of the face via the

Gasserian ganglion and the divisions of the fifth nerve.

(3) *In the ætiology of all three conditions one or more of the three factors that are known to affect the endocrine-autonomic system—namely, infection, reflex irritation, and psychical trauma—appear to be of paramount importance.*

Alopecia Areata.

If one reviews the discussions that have for years centred around the ætiology of alopecia areata, one finds that there have been two main antagonistic theories—the parasitic and trophoneurotic. While the majority of dermatologists accept the latter, there are still some who cling to the former, at any rate in certain cases. Jacquet spent the best part of his life in seeking to prove the non-contagiousness of alopecia areata, and to establish the trophoneurotic view. The epidemics of it that have been reported can be explained partly, as Sabouraud[22] has pointed out, owing to an error in diagnosis between the bald patches following contagious impetigo and true alopecia areata, and partly owing to the occurrence in institutions or schools of one or a few cases of the latter, and the unconscious or deliberate production of bald patches by pulling out the hair (as in trichotillomania) on the part of other children, in order to excite the interest, and perhaps obtain the exemption from work accorded to the genuine cases, as in the epidemics reported by Haldin-Davis.[23]

It has, however, always been a mystery to me how anyone, apart altogether from clinical observations on the evolution and associations of alopecia areata, could possibly entertain the parasitic theory of its causation after a careful study of the remarkable series of changes that constitute the life-history of a patch from its beginning to its final recovery. I can only briefly summarise the most important points:—

(1) A patch of alopecia areata appears suddenly by the fall of a tuft of hair. In the early stages there is capillary dilatation, so that the patch is pinker than the surrounding skin. Sabouraud has described this erythema occurring as a sort of "pre-alopecia roseola" before the fall of hair. In older patches, on the other hand, the colour is paler than the unaffected skin. This initial erythema is common to alopecia areata, scleroderma, and vitiligo. Lévy-Franckel and Guillaume[24] have described changes in the capillary circulation of alopecia areata and vitiligo, as observed with the capillaroscope, which they consider characteristic of sympathetic nerve involvement. It is possible that, as Wright[25] suggests in a recent paper, the fall of hair in alopecia areata is due to interference with the vascular supply of the hair.

(2) Years ago Sabouraud noted that one of the earliest histological changes in alopecia areata is a disturbance of pigmentation at the site of the affected hair papillæ. There is what Besnier termed a pigmentary ataxy—i.e., hyperpigmentation of one part with depigmentation of another, exactly comparable to that which occurs in vitiligo.

(3) This redistribution of pigment is clearly seen in the so-called "exclamation-mark" hairs, which are for practical purposes the hall-mark of alopecia areata. More than any other feature, I think they give us the clue to the immediate cause of this variety of alopecia.

The exclamation-mark hair is usually from 4 to 6 millimetres, occasionally a little over a centimetre, in length; the proximal portion is thinned from atrophy, devoid of pigment, and ends below in a white "dry" bulb, represented by the dot of the exclamation mark; the distal portion is relatively thickened, club-shaped, and deeply pigmented. Sabouraud[26] has shown very clearly how this exclamation-mark hair is formed. If one pulls out a number of dead hairs from the border of an actively spreading patch of alopecia areata, and examines them microscopically, the majority will be found to differ in no way from those that fall after an acute infection, but a few, which would have become exclamation-mark hairs, will show us how these are formed.

At one or more points along the shaft of the hair the strands will be seen to become dissociated, exactly as in trichorrhexis nodosa, and at these points the hair cracks; below the fracture one sees the hyperpigmented bulbous end of the exclamation-mark hair, and proximal to this the atrophied, depigmented part terminating in the dead bulb. I wish particularly to emphasise:—

(*a*) The redistribution of pigment whereby the part near the root becomes depigmented, the bulbous end hyperpigmented—the pigmentary ataxy, which characterises vitiligo, already referred to

(*b*) The atrophy of the hair, which does not occur in parasitic infections such as ringworm.

Now of the affected hairs on a patch of alopecia areata, only a few take on the exclamation-mark form, the rest fall entire, atrophied and depigmented near the bulb, but without going through the exclamation-mark stage.

The real significance of the exclamation-mark hairs is that, apart from alopecia areata, they are met with, so far as I know, only in two other conditions—namely, after epilation with the X rays, and by the internal administration of thallium acetate. The loss of hair in alopecia areata, after X rays, and as a result of thallium acetate, is practically identical in type, and due to *inhibition* of the function of the hair-forming papillæ. The majority of the hairs fall suddenly and completely, but some, more resistant, perhaps, in the case of alopecia areata and thallium alopecia, or which have not received quite the full dose of X rays, go through the exclamation-mark stage.

It is probable that the epilatory action of X rays, as well as the trophic changes in the skin that excessive dosage may produce, are due to their action on the sympathetic nerve-supply of the hair and skin, or of their blood-vessels. It is certain that this is the action of thallium. Wadia, working with Dixon,[27] has shown that the effects of thallium are due to its action on the autonomic system; it diminishes the resistance of the sympathetic nerve-cells to various stimuli—e.g., to the Faradic current. Its action is more marked on the sympathetic than on the parasympathetic. Like so many drugs, it has a double and contrary effect; it destroys the existing hair, but also in small doses stimulates new growth. This accounts for the fact that, after thallium epilation, regrowth of the hair occurs much more rapidly than after X ray epilation.

As Dixon suggests, this action of thallium on the hair, so similar in its objective results to the phenomena observed in alopecia areata, affords an additional argument in favour of the sympathetic nerve origin of the latter. Histologically the loss of hair produced by thallium acetate is found to be due to failure of the process of transition from the large polygonal cells to the stratified cells forming the hair. It is clear, therefore, that this transition, which represents really the process of keratinisation, is under the control of the sympathetic, either directly or through the medium of the blood-supply.

When we come to consider the ætiology of alopecia areata from data afforded by *clinical* experience, we are struck by one significant fact, that two at least of the factors I mentioned as predisposing to the toxic idiopathies clearly also come into play here—viz., peripheral irritation and psychical stimuli; a third factor—acute or chronic infection—might perhaps be included under sensitisation to foreign substances. Moreover, familial or hereditary tendency to alopecia areata, if not so striking a feature as in the toxic idiopathies, is, nevertheless, common enough to exclude the possibility of mere coincidence (22 per cent. according to Sabouraud).

I will briefly review the above factors:—

(1) *Peripheral irritation.*—Jacquet,[28] whose inspiration and imagination were in advance of his time, attributed alopecia areata to a constitutional or hereditary dyscrasia, as revealed by biochemical analyses, combined with a central or peripheral source of nervous irritation (*pelades centrales et pelades réflexes*). He noted the association of alopecia areata

factor is to decide to what extent the biochemical changes found are *the result* of the allergic reaction, and to what extent a metabolic error predisposes to their occurrence.

James Adam,[19] and following him, Haseltine,[20] La Forge[21] and others, have emphasised what they term the toxic factor in asthma, and have shown clearly that many chronic asthmatics may be entirely relieved of their symptoms after an initial treatment of detoxication by means of purgation and the promotion of diuresis and diaphoresis, followed by suitable dietetic rules and insistence on regular outdoor exercise. The same is true in the case of other idiopathies, such as urticaria, angeioneurotic œdema, and the prurigo of Besnier, which is so often accompanied by asthma. Moreover, even in cases of such specific sensitiveness as hay-fever, treatment along these lines may bring about a cessation of the attacks, in spite of exposure to the particular pollen to which the patient is susceptible.

The truth of this contention of Adam and his followers is beyond all question, and may be summed up by saying that, even in patients hypersensitive to a known specific antigen, freedom from active manifestations of such hypersensitiveness can, at any rate in some cases, be obtained by putting the patient under conditions ideal for the development of physical fitness, in spite of his being still exposed to the antigen to which he is sensitised. This is illustrated perhaps most strikingly in patients who are the allergics par excellence—namely, those belonging to the ichthyosis-asthma-hay fever-eczema-prurigo-urticaria syndrome, in whom there is hypersensitiveness to several antigens and multiple symptoms of allergy. If such a person live a completely out-of-door life in suitable surroundings with adequate exercise, combined with judicious heliotherapy, his symptoms disappear as soon as he attains a certain degree of physical fitness; his whole appearance is transformed, he may eat foods with impunity which formerly provoked one or more of his symptoms, and he can handle animals without risk, contact with which previously gave him asthma or attacks of paroxysmal rhinitis. In some cases, as is well known, the mere removal of such a patient from his home surroundings to hospital is sufficient to cause his symptoms to disappear, and, in spite of deliberately exposing him to antigens to which he is sensitised, it may be impossible to make them reappear. On the other hand, a return to his home and his former mode of life, or an emotional upset, may at once cause him to revert to his *status quo ante.* I do not for a moment believe that this effect of a change of surroundings is always due, as some would have us believe, to the patient being sensitised to antigens, such as moulds, dusts, and so on, present in his home; it may be true in a few cases, but in the majority it is not so. In some no doubt the effect is chiefly psychical, in others it is due to the restoration of the metabolic functions to normal.

Unquestionably the treatment par excellence for these allergic patients is, as I have said, to put them under conditions which are most favourable for the proper working of their purely animal functions. In the artificial environment of urban civilisation they are unable to adapt themselves to their surroundings either psychically or physically, and this maladaptation would seem to be partly due, as Bolten suggests, to an inborn insufficiency or hypotonia of the sympathetic and of the accelerator endocrine glands, chiefly the adrenals and thyroid; both their metabolism and their endocrine-autonomic balance is disturbed.

As regards metabolism, the biochemical investigations referred to suggest that it is in the detoxicating functions of the liver that the clue to the problem lies; it would seem, in fact, that this is true both with substances reaching the liver viâ the alimentary tract, and with those introduced parenterally. For example, in the case of metallic drugs such as the arsenical, bismuth, or gold compounds, we know that tolerance of them is largely a function of the liver, and that intolerance may be sometimes prevented by administering glucose in sufficient quantity to ensure an adequate supply for glycogen formation which, as Roger[22] insists, is essential for the antitoxic and detoxicating hepatic functions. I think that the liver may be regarded as the first line of defence, and, when this breaks down, I believe the skin takes on a vicarious protective function, as represented by the various cutaneous manifestations of allergy.

GROUP 2.

Alopecia Areata, Vitiligo, Scleroderma.

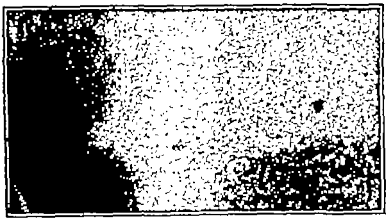
These three conditions form a closely-linked triad, since they not only frequently occur together, particularly alopecia areata and vitiligo, but because all three are often met with in association with diseases of the endocrine-sympathetic system—for example, Graves's disease. The literature concerning them is enormous, but all that need now be said is that the sum total of the clinical and experimental observations published concerning them leads one inevitably to the conclusion that they are all due to involvement of the autonomic nervous system and the associated ductless glands. Nevertheless, the exact mechanism of their production is entirely obscure, and, when one attempts to formulate theories, one is met at once with apparently contradictory facts. For example, scleroderma, as the late Dr. Castle[23] pointed out in his exhaustive review of its literature, occurs so frequently in association with thyroid disorders that there must be a relationship between the two, yet it is found both in Graves's disease and in myxœdema. Dittisheim[24] observed scleroderma in eight cases of Graves's disease out of seventeen, yet the peripheral and generalised form—sclerodactyly—is usually accompanied by symptoms of Raynaud's disease, acroasphyxia, and hypothyroidism. I shall content myself by comparing the three conditions as regards certain features they possess in common, and then briefly deal with each in turn, and record some personal observations upon a few cases.

(1) *All three may occur in a localised and in a generalised form.*—Thus in the majority of cases of *alopecia areata* one or a few asymmetrical patches are found on the scalp or beard region, but in others the loss of hair may become generalised and involve the entire body. *Vitiligo,* though usually extensive and bilaterally symmetrical, may be localised to one area. *Scleroderma,* like alopecia areata, commonly occurs in patches—*morphœa.* Much rarer is the diffuse form, but the pathological changes would seem to be essentially the same, and the two forms may be met with simultaneously or at different periods in the same patient.

(2) *All three may occur in the so-called "band" form.*—Thus *alopecia areata* may rarely be seen to follow more or less the course of the supraorbital nerve, and Sutton[25] has seen it thus succeed an attack of supra-orbital herpes zoster. *Vitiligo* and more often *scleroderma* may also have this "band" distribution. Queyrat and Leri,[26] and Leri and Lamy,[27] have described cases in which both vitiligo and scleroderma were present, followed a zoniform or pseudo-root distribution, and were associated with spina bifida. Hutchinson[28] long ago described cases of scleroderma affecting the distribution of the fifth nerve, and compared it to herpes zoster. Anderson[29] reported a case of scleroderma involving the whole distribution of the right fifth nerve. Alterations were observed not only in the skin, but also in the mucous membranes supplied by the nerve, including the conjunctiva. Moreover, the hair fell out on the same side as high as the middle of the vertex. Sequeira[30] has recorded two cases of scleroderma corresponding in distribution to the first and second divisions of the fifth nerve, and O'Donovan[31] one in which the first and third were affected. Castle also described one in which the first and second divisions were involved. Presumably in these cases the changes in the skin are due to involvement of certain postganglionic sympathetic fibres coming from the superior cervical ganglion, and reaching the skin and mucous membranes of the face via the

vitiligo may result, and the distribution of the leucodermic patches tends to correspond to the sites of election of pediculosis—viz., the shoulders, sacral region, and thighs, but may become widespread.

FIG. 3.



Showing vitiligo developing around small pigmented moles in the left scapular region.

This is shown in Figs. 1 and 2. It is of interest in this connexion that Dore has noted a group of cases of *alopecia areata*, in which severe and long-standing irritation from pediculosis capitis preceded the loss of hair.

(2) *Psychical stimuli.*—The sudden development of vitiligo after a severe nervous shock or accident has, as in alopecia areata, been frequently recorded; Gougerot has emphasised this factor. It was evident in a case to which I shall shortly refer.

There is one feature of vitiligo of great interest, which has not to my mind received sufficient attention, and that is its association with pigmented moles. Sutton,[13] in 1916, reported two cases in which the leucodermic patches surrounded small moles, and christened the condition leucoderma acquisatum centrifugum; in the same year I collected several cases, and also noted the frequency of large pigmented nævi in patients with vitiligo. Figs. 3 and 4 illustrate these two points.

To discuss the full significance of this association would involve a consideration not only of the whole question of cutaneous pigmentation, including Bloch's classical work on the subject, but also that of the origin of nævi, more particularly of the type nævus unius lateralis, of which there are various forms.

Masson, in his recent researches, concludes that the cells of pigmented nævi are of nervous origin. Gutmann and Dalsace have described a case of diffuse unilateral pigmented nævus in which there was evidence of involvement of the orthosympathetic on the affected side—e.g., arterial hypotension, diminution of sweating, and exaggeration of the oculo-cardiac reflex. The pseudo-radicular distribution of the nævus and these signs suggest a malformation localised to the sympathetic nerve centres of the right side of the spinal cord. Similar observations were made by Laignel-Lavastine and Tinel in a vascular nævus unius lateralis.

It would seem that vitiligo is more likely to occur in persons naturally hyperpigmented, and particularly in those who possess large or numerous pigmented nævi.

I will now briefly describe a case in which experiments carried out by Prof. M. S. Pembrey and J. C. G. Dickinson in my clinic seem to indicate involvement of the sympathetic.

The patient came under my care in 1924 for a generalised vitiligo. She gave a long history of repeated attacks of tonsillitis, and in 1914 had three patches of *alopecia areata*. The tonsils were removed in 1916, shortly after which her husband wrote to her from France to say that he had no intention of returning to her. This news produced a serious nervous breakdown, and was followed within a few weeks by the appearance of an extensive *vitiligo*. In 1923 she had an alveolar abscess, and an acute otitis media; 14 teeth were extracted for pyorrhoea. In the same year patches of lupus erythematosus appeared on the hands and feet.

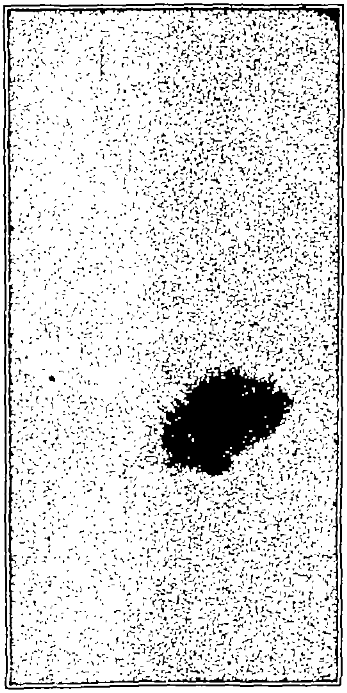
Investigations.—Wassermann reaction negative. Blood pressure 105/74. Test-meal complete achylia. *Loewi's adrenalin eye test positive* on two occasions.

Visible sweating, induced by a hot cradle on three occasions, took place on the non-pigmented, but not on the pigmented areas; on one occasion, however, some sweating of a pigmented area was evoked. But in a case of Addison's disease, with exophthalmic goitre and vitiligo, recorded by Burgess and Warner, in which the hot-air bath alone did not cause sweating, the injection of pilocarpine produced uniform sweating on both dark and light areas of vitiligo.

Other tests with pilocarpine, exposure to ultra-violet light, &c., were performed in my case, and Prof. Pembrey came to the conclusion that the vitiligo was associated with definite sympathetic nerve involvement.

A point of great interest in this case was that, while under observation in hospital, an *erythematous patch* developed on the right thigh, which gradually became transformed into an area of depigmentation and one of hyperpigmentation, the edge delimiting the two remaining pink for some considerable time. This suggests that, as in alopecia areata and scleroderma, there is in vitiligo a pre-erythematous stage before the redistribution of pigment occurs. The combination of alopecia areata and vitiligo, the long story of repeated infections, the signs and symptoms of adrenal-sympathetic exhaustion, and the dramatic onset of the vitiligo after psychical shock were the striking features in this case.

FIG. 4.



Showing vitiligo of the back in the neighbourhood of a large pigmented nævus on the right loin.

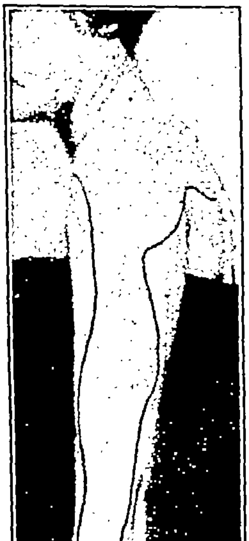
Scleroderma.

I have already referred to certain points of similarity and inter-relationship between scleroderma, alopecia areata, and vitiligo, and cannot here enlarge upon them. I will refer merely to a case of scleroderma (morphœa) involving the left arm and shoulder, associated with muscular wasting and an apparent involvement of the brachial plexus.

This patient, a girl of 24, was sent to me by Dr. C. P. Symonds, and was subsequently investigated by Dr. G. C. Millis. She had superficial patches of scleroderma involving the area shown in Fig. 5.

They were surrounded by the usual "lilac ring," and had begun, according to her own statement, as "red patches." At the same time there was wasting of the muscles of the shoulder-girdle (Fig. 6), particularly of the deltoid and the supra- and infra-spinatus. The patient had complained for some time of pain, chiefly of a "dragging" character, above the left clavicle and in the shoulder extending down the arm. There was seen a definite fullness in the left supraclavicular region, and palpation revealed a soft, ill-defined swelling, the nature of which could not be determined. On X ray examination there was no evidence of cervical rib nor any other bony abnormality, and no opacity in the soft tissues distinct from the surrounding structures. The Wassermann reaction was negative. In view of the distribution of the muscular wasting and of the sclerodermatous change in the skin, Prof. T. B. Johnston was asked to see the patient, and he thought that anatomically the condition suggested a lesion of the brachial plexus, no doubt connected with the supraclavicular swelling.

FIG. 5.



A case of scleroderma, showing the area of left shoulder and arm superficially involved.

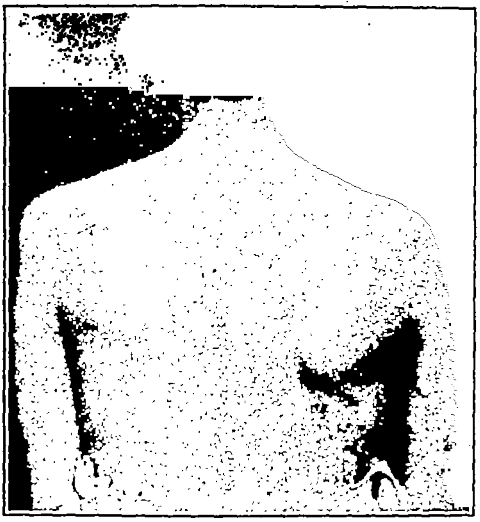
Dr. Millis gave the patient an injection of pilocarpine, which produced rather severe symptoms of collapse with profuse sweating, *but the area of the skin involved by the scleroderma exhibited no sweating,* thus suggesting involvement at any rate of the sudoral nerves in this area.

In this case, therefore, there would seem to have been an involvement of the left brachial plexus of unknown character, associated with partial atrophy of certain muscles, chiefly those supplied by the fifth and sixth cervical nerves, and scleroderma of the skin over the deltoid and suprascapular regions extending down the outer border of the arm to the wrist. I have seen two other cases, both in females, of scleroderma combined with muscular wasting.

I am afraid I have given a very incomplete review of the evidence in favour of the connexion between alopecia areata, vitiligo, and scleroderma and disturbances of the endocrine-sympathetic system, but the literature of these conditions is rich in confirmatory evidence upon which I have not touched. So far as our knowledge goes at present it would seem that the normal process of keratinisation in the epidermis which is disturbed in ichthyotics, the formation of the hair, the control of pigmentation, and what may be vaguely termed the normal nutritional processes in the skin, which is upset in scleroderma, apart from the secretion of the sweat and sebum and the cutaneous circulation, are all under the control of the endocrine-sympathetic nervous system. No doubt there are different groups of sympathetic nerve-cells and fibres controlling these various functions.

In alopecia areata, vitiligo, and scleroderma we meet with cases in which the disturbance is localised and in which it can be connected with a definitely regional area of nerve involvement. Such cases I have mentioned, and they are of paramount importance in establishing my thesis. In other cases the three conditions are more or less generalised, and it is then that we find as a rule symptoms not of local nerve lesion, but of a widespread disturbance of the endocrine-sympathetic system as a whole, such as Graves's disease, simple hyper- or hypo-thyroidism or pituitarism, Addison's disease, profound post-infectional or emotional exhaustion, &c.

FIG. 6.



The same case, showing wasting of the left shoulder-girdle.

Clinically we find that it is just those factors which are known to affect the sympathetic and the endocrine glands, that so often obtrude themselves upon our notice in alopecia areata, vitiligo, and scleroderma—viz., heredity and familial influences, psychical shock, worry or nerve-strain, acute or chronic infections, and peripheral sources of reflex irritation. We can understand that just as a local lesion, such as spina bifida or a meningo-myelitis, might lead to involvement of the sympathetic nerve cells or fibres controlling one function—e.g., sweating or pigmentation, so a general cause, such as an infection, may have a similar selective action.

CONCLUSION.

The title I chose for these lectures, "The Relationship of Dermatology to other Branches of Medicine," affords so wide a scope that I could without difficulty have prepared another series dealing with aspects of the subject upon which I have not touched at all. I have tried, however, throughout to emphasise one fact—namely, the great importance of the skin as a vital organ, both in health and disease. An appreciation of this is, I believe, gradually gaining ground; nevertheless, ignorance of the most elementary principles of the physiology and pathology of the skin is, it must be admitted, widespread among our profession. I believe this to be due partly to the fact that dermatology has been practically ignored in the qualifying examinations, and partly to faulty teaching of the real significance of cutaneous disorders and eruptions in relationship to general medicine. One does not wish to increase the task of the already overburdened student, but it seems to me that he might profitably spend more time studying the surface changes in the skin and accessible mucous membranes, indicative of metabolic errors or "the beginnings of disease," and be reasonably excused much irrelevant matter.

The ten years that I have passed in active dermatological practice since the war have taught me chiefly the following lessons: (1) First and foremost, the fundamental importance of making an accurate diagnosis. (2) To consider all possible *external* factors,—traumatic, irritant and infective,—before approaching the question of internal predisposing causes; this lesson I have learnt from bitter experience. (3) The importance of a complete routine examination of one's patients, and the folly of accepting the findings of others. (4) The value of urinary examination in specimens taken at different times of the day in gauging the metabolic functions of a patient. (5) The influence of acute or chronic infections in the ætiology of banal cutaneous eruptions. (6) The growing importance of the psychological factor in dermatology, as emphasised by O'Donovan and others. (7) The influence of hereditary and familial tendencies. (8) Lastly, to consider the habits, mode of life, and surroundings of one's patients, and to determine to what extent they can be modified, in order to approach as nearly as possible those demanded by a healthy animal.

If dermatologists have become more and more indebted to the expert knowledge of other specialists, from the anatomist to the psychologist, I like to think that to some extent the debt is mutual.

I wish to acknowledge the invaluable help and criticism given to me in the preparation of these lectures by Dr. T. Izod Bennett.

A STUDY IN ENCEPHALITIS.

BY THOMAS F. MACLAUGHLIN, M.D.,
PH.D. ROME, B.S. DUB.,
LATE CLINICAL ASSISTANT IN THE DEPARTMENT OF PATHOLOGY,
BETHLEM ROYAL HOSPITAL, LONDON.

THE following study deals with 28* cases of non-epidemic encephalitis, the outstanding features of which were agitation and depression. In all of them a post-mortem examination showed either active inflammation or the effects of antecedent inflammation in the region of the basal ganglia, and a gliosis not confined to the region of the basal ganglia. In six cases the gliosis in the frontal region had become so extreme as to give the appearance of a tumour formation with hæmorrhage.

Encephalitis, apart from the epidemic or lethargic variety, has been known for many years. The frequency of its incidence to-day has not met with general recognition, first because of the predominance of the epidemic variety, and secondly because the clinical manifestations are so indeterminate. The connexion between pancreatic deficiency and agitated melancholia or its milder manifestation, the anxiety neurosis, has been known since 1923. This work, which was done at Bethlem Royal Hospital, London, was based upon the surface tension readings of the serum and is supported by the blood-sugar observations of Farran-Ridge, Mann, and others, as well as by the post-mortem examinations and the clinical results obtained by treatment. Recent observations appear to show that this abnormal blood state is an immunity phenomenon and that such cases are liable to low-grade infections and inflammations which are often but not necessarily bacterial. Many cases of *Bacillus coli* infection and some of furunculosis show this abnormal blood condition. A majority of such cases of agitated melancholia have proved on microscopic examination to be cases of encephalitis. As a result of these observations the question arose whether or not the relation between encephalitis and pancreatic deficiency is constant. Without exception all the cases of encephalitis investigated showed corresponding pancreatic changes. Observation of a series of cases of encephalitis of different types leads to the conclusion that so long as the surface tension range of the serum remains abnormal the encephalitis is still active. Further facts pointing to the connexion between pancreatic deficiency and encephalitis are the increased sugar in the cerebro-spinal fluid, in encephalitis, and the frequency of diabetes—generally in elderly relatives—in the families of encephalitics. It is worthy of note that encephalitic patients very seldom pass sugar and that none of the cases investigated actually had pancreatic diabetes.

CASE 1.—Clergyman, aged 23, was admitted on March 30th, 1927. He had always been in good bodily health, except for partial blindness for three months in 1923 and diphtheria in 1920. In October, 1926, he became depressed and feared insanity, after which he suffered from restlessness, failure to concentrate, ideas of persecution and self-accusations of immorality. He left home and was found by the police wandering in London. He was taken to Moorcroft where he became violent and made a vigorous attempt to castrate himself. He was transferred to Bethlem, where he revealed auditory hallucinations but no memory defects. He was quiet and took his food. Under treatment with Secretogen he improved greatly, lost the confusion and began making plans for his future. Then there was rapid deterioration, he became restless and confused again, his memory failed, he became violent and noisy, his heart sounds were poor and his heart dilated. He weakened rapidly and died on July 20th, 1927.

Pathological and Post-mortem Findings.

Urine.—April 4th, 1927. Deposit of oxalates and stellar phosphates.

Blood.—April 11th. Wassermann and van den Bergh reactions negative. Surface tension range: 42·5 to 41·5 dynes.

---

* Of the cases mentioned, seven have been selected for publication to show the diversity of types affected and the variability of the clinical picture in this condition.

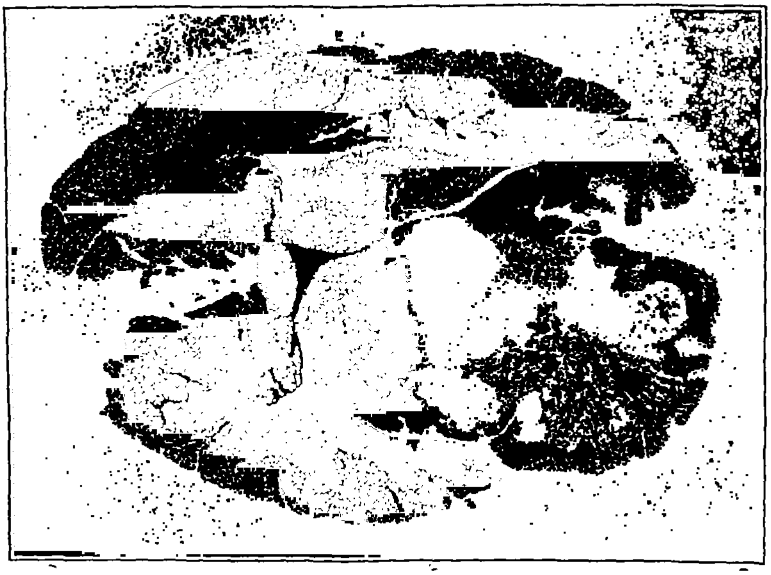
Certified Cause of Death.—(1) Heart failure, (2) lobar pneumonia. The pia and arachnoid mater were found opaque over the vertex. The pancreas was hard and pale; microscopically it showed patchy fibrosis with normal areas, and swelling of the lining of the ducts with cellular denudation. Sections of the brain showed an increase of glial elements and marked engorgement of the smaller vessels with perivascular exudation. These conditions were especially noticeable in the region of the basal ganglia.

CASE 4.—Clerk, aged 46, was admitted on Nov. 5th, 1927. The patient was always in good health. After his discharge from the army it was noticed that if upset he had sudden outbursts of temper. On Sept. 15th, 1927, he was sick at his office and vomited. He went home and was treated for "flu." He was restless during the night from then on. There was reversal of the sleeping habit and he refused food. There is a history of his having been treated for a large carbuncle on the neck in 1917. On admission his physical examination showed general muscular weakness and anæmia and signs which suggested organic disease in the central nervous system. The pupils were unequal, irregular, and sluggish. There was a positive Romberg sign. He was indifferent, spent most of his time huddled up on his bed, and sometimes wandered aimlessly about the ward. His replies to questions were inaccurate and irrelevant. There was a definite nominal aphasia. His memory for recent and remote events was defective. His emotional reaction was one of happy indifference. His thought-content and emotional reaction were in complete disharmony. He was thought at first to be a case of general paresis because of his acute confusional state with aphasia and other physical defects, all of which suggested an organic reaction. After the examination of the blood and cerebro-spinal fluid on Nov. 11th, however, he was treated for pancreatic insufficiency. He died on Nov. 24th.

Pathological and Post-mortem Findings.

Urine.—Nov. 8th. Specific gravity 1032, alkaline; heavy deposit of phosphates but no albumin, sugar, acetone, pus, or renal casts. Nov. 23rd: Acid with a trace of albumin. Deposit of about 2 per cent. pus cells. The pus cells showed a small Gram-positive diplococcus and a slender Gram-negative bacillus.

FIG. 1 (Case 10).



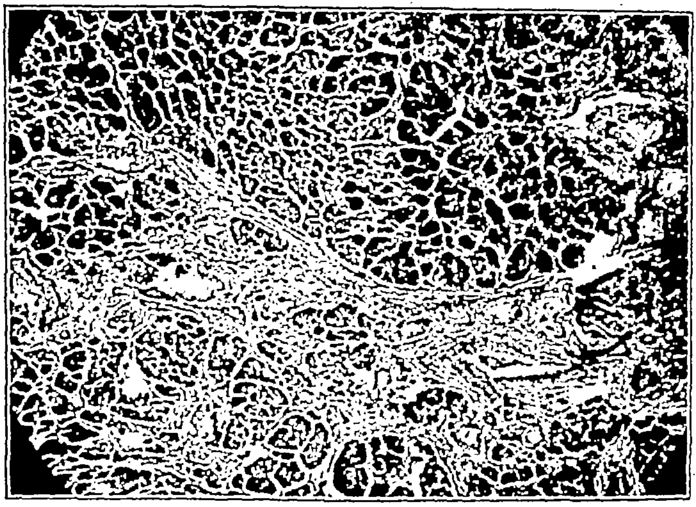
Glioma in the frontal region. Engorgement of basal ganglia.

Blood.—Nov. 11th. Wassermann reaction negative. Surface tension range 45 to 45·5 dynes (on Nov. 23rd, 45 to 45 dynes). Van den Bergh reaction positive.

Cerebro-spinal Fluid.—Nov. 11th. Wassermann reaction negative; Noguchi reaction positive; colloidal gold test, no change. Chlorides 0·71 per cent. Nov. 23rd: Chlorides 0·70 per cent.; contained 550 cells per c.mm. practically all red cells.

Blood Urea.—Nov. 23rd. 48 mg. per 100 c.cm. Urine urea 3 per cent. Ratio 1:60. On these figures the slight rise in cerebro-spinal chlorides between Nov. 11th and 23rd would be accounted for by meningeal irritation.

FIG. 2 (Case 10).



Pancreas in same case as Fig. 1.

Certified Cause of Death.—(1) Subacute encephalitis; (2) respiratory failure.

The dura mater was injected with blood and the veins and sinuses were dilated. The pia and arachnoid were red and injected and were thick and opaque in places. The convolutions were lead-coloured with marked injection. A large tumour was found in the right frontal lobe. Sections presented exactly the same conditions as in Case 1. The pancreas was red and injected but otherwise normal to the eye. Under the microscope, sections showed increase of fibrous tissue—very marked in places—with many areas of hæmorrhage into the substance.

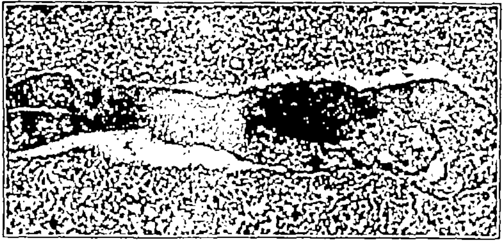
CASE 8.—Tobacco merchant, aged 61, was admitted on Sept. 21st, 1926. He was said to have been a hard-working, quiet man who enjoyed fairly good health. He was subject to influenza and there was a history of diabetes in the family. He was sent to Bethlem Royal Hospital after he had fallen nine feet from a window on to a lawn. He suffered only slight cuts, but was dazed, agitated, and confused. His clinical notes state that he had retired from business six months before on doctor's orders because of anxiety. Investigation by his son showed losses. His son stated that at times he had made "hare-brained schemes for business development." On admission he was in fair condition. His pulse-rate was 64 and regular. There were no murmurs. There were a few moist sounds in both lungs. He became very depressed and said everyone had deserted him, and seldom spoke. There was no history of delusions or hallucinations. There is a question whether he showed reversal of the sleeping habit. His depression and agitation increased. After being treated with Secretogen as a result of showing diminished surface tension range he improved mentally and physically. This improvement was maintained from Nov. 14th, 1926, until April 2nd, 1927, when he showed a temperature of 97·6°, and a pulse-rate of 120, and a respiration-rate of 30. In the lungs were signs of basal œdema. The abdomen was retracted (he had vomited) and there were signs of an old hemiplegia. Digitalin was given but he died the same night.

Pathological and Post-mortem Findings.

Urine.—Sept. 22nd. Specific gravity 1022, alkaline, deposit of phosphates, and trace of sugar, but no albumin, acetone, pus, or renal casts. Oct. 22nd: Specific gravity 1034, alkaline, deposit of phosphates, but no albumin, sugar, acetone, pus, or renal casts.

Blood.—Oct. 7th. Wassermann reaction negative. Nov. 12th: Wassermann reaction negative; surface tension range 48·5 to 41·6 dynes.

FIG. 3 (Case 10).



Thrombus in brain in a case of encephalitis.

Certified Cause of Death.—(1) Broncho-pneumonia and heart failure; and (2) arteriosclerosis.

The pia and arachnoid were somewhat œdematous, and slightly opaque. The liver was dark and bile-stained. Both kidneys were red. On section the pyramids were indistinct and the cortex irregular. The capsule was adherent. Sections from the brain showed exactly the same conditions as in Case 1. The pancreas was soft. Sections showed marked fibrosis.

CASE 10.—Station-master, aged 60, was admitted on Jan. 26, 1925. He was said to have enjoyed fairly good health. Fifteen years before his final breakdown he had what was then diagnosed as a "nervous breakdown" of some months' duration and was treated at home. Eight months before his admission he began to complain of forgetfulness and inability to concentrate. After a month he took a vacation and stopped work for five months. On *his return he found things still more difficult and was forced* to resign absolutely. He then began to complain of severe and almost continuous headaches. On admission his left pupil was fixed and the right pupil gave a just perceptible flicker. Both pupils reacted to accommodation. He was depressed and agitated. These moods seemed to depend on the severity of the headache. His conversation was largely inconsequent and his memory for both recent and remote events was poor. His reflexes were normal with the exception of the pupils and the bladder, which showed considerable leakage before micturition. A week after admission he became hallucinated, noisy, and restless. On sedatives he became apathetic, incoherent, and faulty in his habits. His pulse-rate was 100 and regular. His temperature was 97°. On Feb. 5th his pulse-rate went to 120 and then dropped to 70. He was then semi-conscious. His temperature was subnormal. On Feb. 7th, 1925, he suddenly collapsed. His pulse became feeble and his breathing shallow, and he went into a state of coma. He died the same day.

Pathological and Post-mortem Findings.

Urine.—Jan. 27th. Specific gravity 1012, amphoteric reaction, deposit of phosphates; no albumin, sugar, acetone, renal casts, or pus. Feb. 5th: Specific gravity 1010, urea 1·1 per cent., acid, a few granular casts, and leucocytes; a trace of albumin, but no sugar or acetone.

Cerebro-spinal Fluid.—Feb. 5th. No lymphocytosis. Colloidal gold test, no change. Noguchi reaction definitely positive (no blood). Feb. 7th: No lymphocytosis. Noguchi test definitely positive. Colloidal gold test, no change. Wassermann reaction negative.

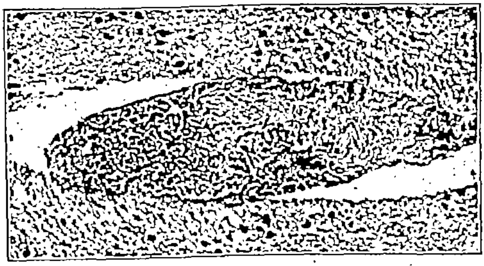
Blood.—Feb. 5th. Urea, 23 mg. per 100 c.cm. Ratio to urine urea 1:60. Feb. 7th: Wassermann reaction negative. Surface tension range 45·5 to 40 dynes; repeated, 45 to 45 dynes.

Certified Cause of Death.—(1) Encephalitis lethargica; and (2) respiratory failure.

The pia and arachnoid were normal but congested. The convolutions showed large effusions of blood over the right frontal pole and other small areas on the left temporal region. *The liver was fatty. The kidneys were* pale, with narrow cortex and no distinction between the cortex and the pyramids. On section a large glioma was seen in the right frontal region. Sections of the brain showed exactly the same conditions as in Case 1. The artery to the pancreas was blocked by a calcareous patch. There was softening of the body and the tail was hard and white. Sections showed extensive areas of fibrosis.

CASE 21.—Secretary, aged 38, was admitted on Dec. 16th, 1922. He was a well-educated and highly intellectual man, brought up with narrow Nonconformist views. He became a solicitor but after a "religious upheaval" he threw up the law and took up Y.M.C.A. work. He married at 28 and was looked upon as a very competent and capable man. He was sent to India just before the war and held a prominent post in the Y.M.C.A. there. Owing to the war he had to remain in India, where he worked continuously until his health broke down in 1921, and eventually he was sent back to England early in 1922 with dysentery *and malaria. He was treated by Castellani* and made a good recovery, and by August, 1922, he began to take up his work again. In November he undertook a lecture tour in Ireland, where he had one or two attacks of "influenza," which did not, however, incapacitate him. On Dec. 14th he received a telegram in Dublin saying that his mother had pneumonia, and he returned to London at once. He was met at the station by his brother with the news that she was dead, and he became emotional. His wife took him to a hotel, where the emotional disturbance increased, and during the night he became hallucinated, excited and confused. On Dec. 15th he was seen by Castellani, who pronounced him free from malaria and dysentery, and also by Sir F. Mott, who could find no neurological signs. The excitement persisted, he became noisy and violent, and he was admitted to Bethlem the following day. On admission he was well nourished and in good muscular condition. His heart was dilated and his pulse-rate 160. There were no murmurs. The apices of both lungs were dull and the bases congested. The pupils were pinpoint and reacted to light. Mentally he was in a state of acute toxic delirium. It was impossible to obtain his attention. He was restless, noisy, shouting meaningless words and phrases, and incontinent. He required tube-*feeding.* No physical signs presented themselves, though he occasionally showed a slight rise of temperature to not more than 100°. He wasted rapidly and the delirium subsided, until by the seventh day it was possible at times to keep his attention momentarily, but he never became properly accessible. He died suddenly on Dec. 24th, 1922.

FIG. 4 (Case 21).



Organising thrombus in vessel of brain.

Pathological and Post-mortem Findings.

Urine.—Dec. 19th. Specific gravity 1080, acid, a trace of albumin, and a deposit of uric acid. No sugar, acetone, renal casts or pus.

Cerebro-spinal Fluid.—Dec. 22nd. No lymphocytosis. Noguchi test gave definite flocculence. The Wassermann reaction was negative and the colloidal gold test showed no change.

Blood.—Dec. 22nd. Wassermann reaction negative. Serum strongly anticomplementary. Moderate leucocytosis, of fourteen thousand, and marked vacuolation of the red corpuscles. No definite malarial parasites could be found. Urea in urine 2½ per cent., equals 2500 per 100 c.cm. Urea in blood 72 mg. per 100 c.cm. (fever). Ratio 30 : 1. Ratio in nephritis 10 : 1. Average blood-urea 40 mg. in 100 c.cm.

Brain Sections.—Dec. 28th. There is no evidence of malaria.

Certified Cause of Death.—(1) Cerebral œdema; (2) cerebral hæmorrhage; and (3) cardiac dilatation.

The veins and sinuses of the head were congested. The pia and arachnoid were very congested over the whole of the vertex. On the right side there was a subpial hæmorrhage about 2 inches in diameter, spread over the surface of the hemisphere. Sections showed the vessels dilated and thrombosed. There were many small hæmorrhages and perivascular infiltration. The neurologia was increased and there was chromatolysis of nerve cells. Sections from

Accessory

suprarenals were numerous and prominent. Sections of the brain showed exactly the same conditions as in Case 1. The pancreas was shrunken, with multiple hæmorrhagic areas. Sections showed dense masses of fibrous tissue throughout the gland. There were large smooth empty cavities (fat necrosis) and very little normal tissue remained. The vessels were thickened and thrombosed.

CASE 26.—Married woman of 50 was admitted on May 19th, 1928. She had two children: a boy of 14 and a girl of 16. She was said by her husband to have been always nervous and highly-strung. Her husband separated from her ten years before her death because of her temper and a sex-habit to which she was addicted. In 1920 she was operated on for floating kidney and appendicitis, and made a good recovery. In 1923 she complained of extreme physical exhaustion and depression. She was treated medically at home and recovered some measure of strength. In February, 1928, she again complained of great weakness and was forced to stay in bed. She could not sign her name and gradually began to ramble in her speech. She was then very irritable, depressed and agitated. Three weeks before admission she left her home at night and was found by the police wandering in her night-dress. As there was no improvement, she was admitted to Bethlem as a voluntary boarder on May 19th, 1928. Physically she was in a very poor condition, with sickly pallor of the face and cyanosis of the lips. There were no heart murmurs. The blood pressure was 114–72 and the heart-sounds were weak. Her breathing showed a tendency to tubularity. The pupils did not react well to light. Her abdomen was rigid in the left and right iliac regions owing to prolonged constipation. She was drowsy for long periods, lying in an almost comatose state. She could be readily roused, when for a few moments she answered questions intelligently. She then rambled in her speech. There was marked confusion, and disorientation was complete in all spheres. The drowsiness was enhanced by bilateral ptosis. During her eleven days in hospital there was no mental change. Physically she failed very rapidly. On May 29th her temperature reached 105°. She was quite comatose and breathing rapidly. There was a patchy broncho-pneumonia. She died on May 30th, 1928.

Pathological and Post-mortem Findings.

Urine.—May 23rd. Specific gravity 1012, amphoteric and light cloud of albumin. Deposit of pus, but no sugar, acetone or renal casts.

Blood.—May 24th. Wassermann and van den Bergh reactions negative. Surface tension range 48·5 to 40 dynes.

Cerebro-spinal Fluid.—May 30th. No lymphocytosis (10 per mm. 3). Noguchi test positive. Colloidal gold test 0012332100,0 (meningitic type). Chlorides 0·68 per cent. at the highest (below normal).

Certified Cause of Death.—(1) Heart failure; (2) broncho-pneumonia; and (3) encephalitis.

The pia and arachnoid were engorged and the convolutions very red. There was no excess of cerebro-spinal fluid. The liver showed some fibrosis. The vessels of the brain were very obvious on section. The colour of the white matter was darkened to a pale buff. Sections presented exactly the same features as in Case 1. The pancreas was normal to the naked eye. Sections showed increase of fibrous tissue—very marked in places—with areas of hæmorrhage into the substance.

Encephalitis, therefore, appears to be a low-grade inflammatory process which occurs in persons with an abnormal blood serum and is always associated with pancreatic deficiency.

My thanks are due to Dr. J. G. Porter Phillips, the physician-superintendent of Bethlem Royal Hospital, for his advice and help in the preparation of this paper, and to the Governors of the institution for permission to work in their laboratory. My thanks are also due to Dr. C. Lovell and his staff for their assistance.

THE SUNDERLAND HOSPITALS.—The Monkwearmouth and Southwick Hospital, at Sunderland, is to be removed to another site, the present building being almost entirely surrounded by a factory. The new hospital will provide more than 100 beds—nearly double the present number—with facilities for extension. The cost is estimated at £100,000. Sunderland Royal Infirmary is also in course of enlargement. Princess Mary last year opened the block named after her, and the second part of the scheme, the building of pathological and bacteriological laboratories, is now being started. Next will come an administrative block which will cost £40,000, and is expected to be completed within the next 12 months.

THE INDUCTION OF INFLAMMATION IN THE TREATMENT OF MALIGNANT AND OTHER LOCAL DISEASES.

BY HAROLD BURROWS, C.B.E., F.R.C.S. ENG.

Bernhardt and Strauch[4] state that intravenous injection of isamine-blue reduces the rate of growth and decreases cachexia in certain cases of inoperable cancer. While trying to find a vital dye specific for cancer cells, and following their work, I found that isamine-blue, given intravenously or intraperitoneally, sometimes stained grafted tumours growing in the flanks of rats and mice. At first it seemed as though isamine-blue might have some degree of special affinity for malignant cells, but subsequent experience showed that isamine-blue, when administered during life, collects in inflamed tissues so as to make them a pronounced blue, while the normal tissues—with the exception of the liver and perhaps other components of the reticulo-endothelial system—remain quite unstained. Other colouring matters become localised in inflamed tissues in a similar way. Some of the preliminary observations which led to a recognition of this fact are as follows:—

(1) A mouse was given an intraperitoneal injection of 0·3 c.cm. of a 0·5 per cent. solution of isamine-blue in normal saline. Post-mortem examination six days later revealed some small patches of blue in the omentum, deep staining of the axillary and anterior mediastinal glands (such as would be expected after an intraperitoneal injection of the dye), and pronounced staining of the tissues immediately surrounding a parasitic cyst of the liver. No prominent blue coloration was present in any other tissue.

(2) An old albino rat was given an injection of 2 c.cm. of a 0·5 per cent. solution of isamine-blue in normal saline into the left femoral vein. Four hours later the rat was found to have died of hæmorrhage from the punctured vein. Post-mortem examination showed a striking blue coloration of the cæcum, which was the seat of a relatively large non-malignant ulcer.

(3) A rat with an ulcer below the jaw was given a similar intravenous injection of isamine-blue. On the following day the cutaneous edges of the ulcer were stained a distinct blue.

(4) On several occasions it was noticed that when injections of isamine-blue were given to rats who were suffering from scabies of the ears, the dye became localised in the zones of inflammation, each little nodule becoming blue.

(5) When dyes were injected into the femoral vein the groin was epilated, the rats were anæsthetised, the skin of the groin was disinfected with methylated spirit and lysol or with methylated spirit alone, an inguinal incision was made, the femoral vein was exposed, and the drug was injected into it, the wound was closed with a single stitch, and a final disinfectant was applied. Special care was taken to prevent any escape of the dye into the field of operation. In spite of these precautions a varying degree of staining of the epilated skin was repeatedly observed, and in cases where the small wound did not close by primary union the edges of the open wound were stained blue.

(6) Similar observations were made when trypan-blue was used; the following is a particular instance. An old albino rat which happened to be suffering from otitis media was given an injection of 3 c.cm. of a 0·5 per cent. solution of trypan-blue into the left femoral vein. Three days later the skin of the right side of the face was swollen and stained blue and the right eye was protosed.

From these and similar observations it was concluded that isamine-blue and trypan-blue, when injected into the peritoneal cavity or directly into the blood stream, have a special tendency to become deposited in tissues which are inflamed. Numerous experiments were subsequently carried out to test this general conclusion, the purpose being to produce a local inflammation and then to observe if a drug injected into the peritoneal cavity or into the blood stream would accumulate in the artificially inflamed area.

The following methods of causing inflammation were employed:—

(1) *Application of Chemical Irritants to the Skin.*—Epilation of a small area in the right flank or of a right limb was effected with sodium sulphide, and a swab wet with methylated spirit or chloroform was then kept applied to the epilated area while the drug to be tested was injected into the left femoral vein. The localisation of dye in the inflamed skin in these rats was definite, though usually not intense; but the inflammation of the skin was only mild.

(2) *Injection of an Irritant Beneath the Skin of the Right Flank of a Normal Rat before the Intravenous Injection of a Dye.*—The irritants used were Coley's fluid, sterile agar-agar (1 per cent. solution in distilled water), neutral gum (5 per cent. solution in distilled water), kaolin suspended in 5 per cent. solution of gum in distilled water, and kaolin suspended in distilled water. Turpentine and chloroform were also tried, but hypodermic doses of either of these drugs in amounts as small as 0·1 c.cm. caused the death of the animal almost immediately (i.e., in three of the four animals used. In the survivor no localisation of dye occurred at the site of injection of the chloroform). Coley's fluid did not appear to cause much, if any, inflammation in mice, but some success attended its use in rats. Of the reagents tried, agar, which was suggested to me by Dr. Piney, appeared to be the best, and the others were discarded. A 1 per cent. solution in distilled water sets as a jelly at the ordinary temperature of the laboratory. Nevertheless, even in this state, it can be drawn up through a medium-sized serum needle and injected by a hypodermic syringe. The usual amount given to rats was 1 c.cm.

(3) *Injection of sterile irritants (usually 1 per cent. agar-agar) into grafted tumours growing in the right flank*, followed by intravenous or intraperitoneal administration of the drugs to be tested.

(4) *Application of diathermy to the thigh of a non-tumour-bearing rat shortly after an intravenous injection of trypan-blue* (one experiment only).

The drugs tested for localisation in these experiments were, with the exception of India ink, chiefly vital dyes, and included India ink, trypan-blue, trypan-red, isamine-blue, Congo-red, water-blue, erythrosin, proflavine, and safranin.

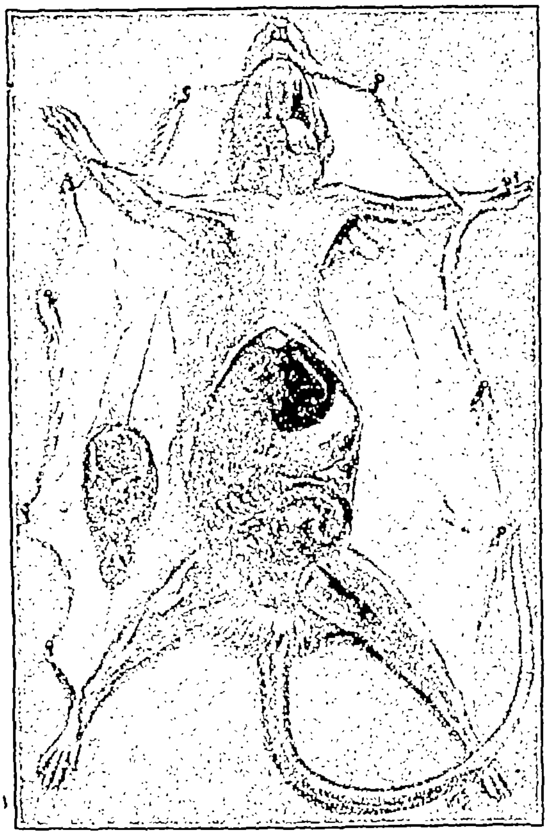
It was found that to get the best results an interval must be allowed between the injection of the agar and the intravenous administration of the drug to be tested. Poor results were obtained if this interval was shorter than two hours, and usually two and a half to three hours or more were allowed to elapse. With peritoneal injections of dye the inflammatory agent may be injected at the same time. The liver in particular has such an avidity for India ink and dyes, and fixes them so securely, that unless the inflammation induced by the agar has reached a sufficiently advanced stage by the time that the dye is circulating in the blood little or no dye will be available for the inflamed tissue. With intraperitoneal injections the passage of the dye into the blood stream is a slow process, and if the dye be injected by this route and the agar be given subcutaneously at the same time, the agar will have had time to produce a sufficient grade of inflammation before the major part of the dye has entered the blood stream.

Results.

Localisation of the colouring matters used in the inflamed tissues was strongly manifest with trypan-blue, trypan-red, water-blue, and isamine-blue, and it was definite also with Congo-red and India ink. With erythrosin, proflavine, and safranin the experiments were performed once only and the results were indefinite. Diathermy was used as the inflammatory (vasodilating) agent in one experiment only. A young rat was anæsthetised and an injection of 1·2 c.cm. of a 0·5 per cent. solution of trypan-blue in normal saline was made into the left femoral vein. Twenty minutes later the right thigh was submitted for three minutes to a diathermy current. On the following day, when the rat was killed, the tissues of the right thigh in the region treated by diathermy had become stained a uniform, pronounced blue. There was some evidence that the current used had been greater than would be desirable for therapeutic purposes. However, the problem is about to be further investigated with the collaboration of Mr. W. V. Mayneord.

In view of the possibility of treating malignant disease by setting up inflammation in the tumour and so causing it to retain a therapeutic remedy, a careful observation was made of the axillary lymphatic glands of the animals whose grafted flank tumours had been impregnated with colouring matter under the influence of inflammation. But it was found that the dyes were so firmly fixed in the tissues which had been inflamed that the axillary lymphatic glands remained free or nearly free from coloration.

It is possible that if a growth were destroyed by this method the disintegrating products, including the therapeutic agent itself, would ultimately drain away by the lymphatic system and so bring the lymphatic extensions of the original growth under the influence of the remedy. Whether such a process will occur remains to be proved. At any rate the experiments conclusively show that an inflamed tissue can hold and retain various colouring matters circulating in the blood against the competition of the liver and the reticulo-endothelial system generally. In therapeutic practice this competition can be largely eliminated by applying the remedy immediately to the inflamed tissue, either by direct injection into the tissue or into its artery of supply.



Rat with a J.R. sarcoma growing in right flank. One c.cm. of 1 per cent. agar-agar was injected into the tumour, and at the same time 1·5 c.cm. of 0·5 per cent. trypan-blue were injected into the peritoneal cavity. The dye has become concentrated in the inflamed tumour.

General Discussion.

This retention by living, inflamed tissues of certain substances conveyed to them in the blood is clearly a therapeutic principle of very great importance, and it has also a direct bearing on physiology and pathology. The fact itself is not entirely new. Lister and others of his time excess strated that an inflamed tissue could collect etal regions. the white blood cells, and within the l and the spleen quiries have been made into the diss showed some ective organisms when injected an abnormal narr into experimental animals. It has been shown that the organisms, very quickly after their introduction into healthy tissues, appear in the appropriate lymphatics and in the blood stream; whereas if the injection of organisms is made into tissues which are already inflamed the dissemination is retarded or prevented.

In 1924 E. L. Opie[1] showed that certain antigens introduced into a normal rabbit diffuse widely in the tissues, enter the blood stream, and appear in the urine, while the same substances injected into a sensitised animal are fixed at the site of injection and do not get into the blood (cf. Arthus's reaction). G. Spagnol[2] found that if colloidal mercuric sulphide were injected into the auricular vein of a rabbit while a pad of cotton-wool soaked in chloroform was applied for 15 seconds to the animal's side, a sharp black stain of the sulphide was found in the subcutaneous connective tissue under the chloroformed spot when the rabbit was killed—after two hours or eight days. A corresponding experiment on a guinea-pig, using trypan-blue instead of mercuric sulphide, showed a similar deposition of the injected material beneath the area of skin to which chloroform had been applied. Valy Menkin,[3] in a valuable paper recently published, has reported some experiments which demonstrate beyond doubt the fixation of trypan-blue when injected into inflamed tissues. He injected it into the forelegs of rabbits and collected the lymph returning from the treated area by inserting a capillary pipette into a subclavian lymphatic vessel. He found that when trypan-blue was injected subcutaneously into the foreleg of a normal animal the dye readily appeared in the lymph flowing from that leg. But if an inflammatory agent (5 per cent. aleuronat with 3 per cent. starch in 0·5 per cent. saline solution) was injected subcutaneously into the leg an hour or so beforehand, a subsequent injection of trypan-blue into that leg was not followed by the appearance of the dye in the lymph. Menkin mentions an experiment by Opie in which the latter found that a preliminary aseptic peritonitis set up by aleuronat prevents, after an interval of 24 hours, the dissemination of hæmolytic streptococci injected into the peritoneum.

From remote times until to-day clinicians have used therapeutic measures of which the effectiveness can be explained by the principle now advanced. For example, the remedial effects of setons, blisters, cauterisations, counter-irritations, poultices, hot fomentations, active and passive congestion, and sterile fixation abscess may be attributed at least in part to the capacity of inflamed tissues for removing from the blood stream the agents and noxious products of disease. Sunburn and the pigmentation of scars, the disappearance of micro-organisms from the blood stream in the most active stage of typhoid fever, and many other phenomena can be accounted for by inflammatory fixation.

Summary.

(1) Inflamed tissues have the capacity for collecting and retaining many substances carried by the blood stream or injected locally.

(2) If inflammation be caused in any part requiring treatment medicaments can be concentrated in that part and so prevented from damaging healthy organs.

(3) There is reason to suppose that a large variety of remedies may be supplied in a form suitable for use by this method.

I have to thank Prof. A. Leitch, Director of the Research Institute of the Cancer Hospital, who provided facilities for this work. Dr. E. L. Kennaway has been kind enough to suggest and supervise throughout, and the outcome of this experimental inquiry is largely due to him. Dr. A. Piney has given me helpful advice on several occasions. To these, to Mr. W. V. Mayneord, and to the laboratory attendants I am glad to acknowledge my indebtedness.

The work has been carried out at the Research Institute of the Cancer Hospital, London, under a

grant from the British Empire Cancer Campaign, for whose assistance I wish also to express my gratitude.

FACTORS IN FOOT RECONSTRUCTION.

BY C. HOPE CARLTON, M.CH. OXF., F.R.C.S. ENG.,

SURGICAL REGISTRAR, LONDON TEMPERANCE HOSPITAL; LATE REGISTRAR, ROYAL NATIONAL ORTHOPÆDIC HOSPITAL, LONDON.

IN considering the mechanics of the foot I have had the help of Mr. L. N. G. Filon, F.R.S., Professor of Applied Mathematics at University College. After examining the bones of the leg and foot he wrote as follows:—

> "Removal of the astragalus might be expected to give better lateral stability than fusing the tarsus, since in astragalectomy the malleoli will engage the bones on the tarsus which lie immediately below. When the foot is dorsi-flexed in paralysis with weak calf muscles, then removal of the astragalus with posterior displacement would help mechanically, since dorsi-flexion is reduced first by the removal of bone at the fulcrum, and, secondly, by the greater mechanical advantage with which the calf muscles now act. When the deformity is that of plantar flexion, then anterior displacement would be desirable to enable the dorsi-flexors to act with greater advantage, or as an alternative, a stop must be produced to prevent plantar flexion beyond a right-angle."

It is satisfactory to find clinical experience agreeing with the deductions of a mathematician who was examining the bony skeleton for the first time.

I next sought the opinion of a consulting engineer as to whether such a mechanism as the tarsus occurs in any engineering system. Miss Verena Holmes, a member of the Institute of Mechanical Engineers, and of the Institute of Marine Engineers, says:—

> "The arrangements of the muscles and bones in the foot and leg are not analogous to any engineering device within my experience. The engineer, unlike nature, seeks to make each part of a mechanism in which positive motion is created follow a circumscribed path, generally in one plane, and where a complicated movement has to be obtained it is arrived at by the combination of a number of simple movements of different parts. Otherwise, where complicated and indefinite movements take place in mechanisms, these will generally be found to be movements of accommodation, as, for instance, at a universal joint between two parts that cannot be rigidly connected. *Engineers hardly ever combine two functions in one moving part as nature does.* . . . Whitman's operation substitutes a hinge of limited movement for what is almost a universal joint. With the springs that normally limit and control the action of the universal joint out of order, this would seem to be the best thing one can do, if it were not for the disadvantage of shortening. Further, in the Whitman operation there will be greater stability in a sideways direction owing to wider contact between leg-bones and foot, which will withstand better unequal lateral pulls."

The theoretical approach to the problem of tarsal reconstruction therefore agrees generally with the results of surgical practice.

The refashioning of the neck of the astragalus, combined with triple arthrodesis, which is associated with the name of Michael Hoke, has for the last three years been extensively practised in North America. On the orthopædic service at Harvard it is much employed, and their view of it is expressed in a letter I received some time back from Prof. Allison, of the Massachusets General Hospital, who says:—

> "It is a better operation for calcaneus than for equinus. In paralytic calcaneus it gives a most useful foot. Backward displacement is the important essential, and long fixation in plaster is desirable. It has no place in spastic feet, but is very useful in club-feet where manipulation is insufficient."

Emphasis may be laid upon the only two points about which there is any general agreement among those with experience of foot reconstruction. They would all rather deal with calcaneus than with equinus, and they almost all insist on the need of backward displacement.

There is no doubt that Hoke's operation yields good-looking, serviceable feet without instruments. It is also successful in equinus, because it corrects the downward pitch of the neck of the astragalus and metatarsus. No doubt some deformity thus abolished had its origin in muscular paralysis and stretching of the astragalo-scaphoid ligament. My criticism of Hoke's operation is its unnecessary difficulty. As I saw it practised at the Massachusets Hospital, the neck and head of the astragalus were taken out, held in forceps, and cut with an electric saw. In Hoke's words, the operator's aim is first to set the posterior foot which, after removal of the head and neck, is subject to the operator's wishes; and, second, to sink down the moulded head. I suggest that the "setting" is just as well performed after the removal of bone from the head of the astragalus as from the base of the neck. And it is certainly easier to mould the neck in situ, as does Dunn, than to reset and replace. Admittedly an exception might be made in severe equinus, where a very oblique neck would fuse with the scaphoid at too sharp an angle. This angle is avoided when the surplus bone is removed from the base of the neck.

Straight Triple Arthrodesis.

The alternative method of arthrodesis in general use at the Hospital for Sick Children, Toronto, consists in simple excision of the joints between the astragalus, scaphoid, and calcaneus. Relapse is infrequent. Dr. Gallie, in whose service I was privileged to work for a year, has told me that he thinks the slowly progressive form of relapse, which is apt to occur in children under ten, *is due to actual change in the shape of the* bones, such as occurs after arthrodesing operations at the knee-joint in young children. Dr. Gallie's favourite operation is subastragaloid and mid-tarsal arthrodesis with a tendon fixation of the tendo Achilles into the back of the tibia. He says that this operation has the advantage of stabilising the foot, and so allowing the patient to wear a high boot in cases of shortening. It does not shorten the limb; it holds the foot firmly in any desired degree of equinus, and it enables the patient to take weight on the ball of the foot.

The arthrodesis of spastic feet is employed much more in Toronto than in Boston. In a recent letter Dr. Gallie says: "I am strongly of the opinion that mid-tarsal and subastragaloid arthrodesis is an excellent operation for spastic paralysis." He goes on to say *that he has half a dozen beautiful results,* far better than he has ever seen with any other form of treatment.

I have recently performed the Toronto operation on three patients; one had an equino-cavo-valgus, and the other two had almost flail-feet in equino-varus. The operation gave them good plantigrade feet, although the first case still had five degrees of valgus. They have from 30 to 60 degrees of movement at the ankle, and one still wears a calliper to the hip. They all walk from one to five miles, and one kicks a football with the operated foot. Two of them have 2 per cent. anterior displacement, the other has no displacement. Two showed, under the X ray, bony union throughout, and all showed painless firm ankylosis.

Whitman's Astragalectomy.

I have had the privilege of studying a number of astragalectomy patients whilst assisting Mr. Laming Evans at the Royal National Orthopædic Hospital. This method appealed particularly to the mathematician and consulting engineer, who viewed it from a mechanical standpoint. It is very valuable for painful osteo-arthritis of the ankle and subastragaloid joints after fracture or disease of the astragalus. It gives relief from pain on walking, increases mobility, and so improves the shape of the foot as to make recognition of the injured limb difficult. One of Mr. Laming Evans's cases illustrates this: fibrous ankylosis had followed a pneumococcal abscess of the tarsus; after astragalectomy there was 40 degrees of movement at the new joint, no lateral deformity, good stability, and a shapely foot. The patient needed a three-quarter inch cork.

Personal impressions offer the only means of assessing the results of astragalectomy. Sometimes success is undoubted, as in a patient aged 19, from whom Mr. Laming Evans removed the astragalus in childhood. The man now works as a farm labourer, plays football, refuses surgical boots, and wears those obtainable in a village shop. As a rule, however, difficulty of assessment is due to associated paralysis and the length of time over which treatment has been spread.

To 19 consecutive cases at the Royal National Orthopædic Hospital I applied the following test: could the patient, in his present condition, get about well enough to act as a doctor, lawyer, housewife, teacher, or domestic servant? I concluded that 13 of the 19 could have done so, and six of them could do much more. Of the remaining six the disability of three was due to paralysed quadriceps. Another one had a paralytic dislocation of the foot. The astragalectomy was performed 13 times for calcaneo-cavo-valgus, and in 12 of these improvement followed. It was performed seven times for equino-varus, and in five of these improvement followed. These results are similar to those given by J. E. M. Thomsen in 1924, and Wallace in 1916. The paralytic group included 16 cases, of which 15 were improved. The congenital group included four cases, of which two were improved. The posterior displacement, estimated in percentages of foot length, varied from 1 to 12 per cent., with an average of 5 per cent. No definite correlation was established between posterior displacement and functional results; this may have been due to the presence of associated deformities, and the difficulty of measuring posterior displacement. The method was to measure the length of the foot which lay behind the external malleolus, and to speak of this as a percentage of the foot length. The difference in this percentage on the two sides is a numerical measure of the displacement.

Dr. Royal Whitman, in his text-book, criticises Dunn's operation for not giving enough displacement to prevent dorsal flexion. Posterior displacement is admittedly necessary in calcaneus to restore the grip of the fore-foot in walking, but it is equally important that the limb should function as a firm pillar with a stable base. I believe that many patients after Whitman's operation must be seriously handicapped when barefoot on a slippery surface, as in taking a bath, and that Dunn's reconstruction often gives a firm pillar together with good fore-foot grip.

I have had the privilege of studying this operation at the Hospital for Sick Children, Ormond-street, on the service of Mr. H. A. T. Fairbank, and the following remarks are based on 20 consecutive cases of his, with three of my own, treated elsewhere.

The average age of Mr. Fairbank's series was eight years, and the average time since the acute disease six years. In 11 patients there was some variety of equinus, and in the other nine some variety of calcaneus. I found no definite correlation between the quality of the result and the amount of posterior displacement. Feet with a posterior displacement of 4 per cent., 8 per cent., and 11 per cent., all gave excellent results. A comparison of these results with those after Whitman's operation shows an equal amount of posterior displacement, the average in both procedures being about 5 per cent. of the foot length. The actual shortening of the leg after Dunn's operation was trifling, perhaps a quarter of an inch, compared with a shortening of a half to one inch after Whitman's operation. There was a shortening of the foot of about 10 per cent. after Dunn's operation. There was no failure in the series, and in almost every case the result might be called good. Clinically, there was always painless firm ankylosis of the tarsus, although radiograms showed lack of bony union between the astragalus and the cuneiforms. Between these bones there was bony union in two cases only, and in the majority they were widely separated. There was usually bony union between the os calcis and the astragalus, and between the os calcis and the cuboid. After operation all the patients possessed useful plantigrade feet, although five of them had about 20 degrees of varus, two others 5 degrees of varus, and one 5 degrees of valgus. The average movement at the ankle-joint was 50 degrees.

The results are very similar in three Dunn's operations that I have recently performed. All were over 15 years of age. Two were for drop-foot and one for calcaneus. All three have good plantigrade feet with painless ankylosis. In the drop-foot there has been an increase of power in the dorsi-flexors. The calcaneus foot is efficient and shapely.

Summary.

Assessment of the results of foot reconstruction is difficult to express exactly, and must remain a matter of personal impression. My own preference is for the Dunn reconstruction, with an exception for astragalectomy when the astragalus is misshapen or subject to osteo-arthritic changes on both upper and lower surfaces.

The conclusions expressed in this paper have the defect that they are for the most part those of an observer rather than of a doer. It is usually a junior officer who is stationed in the observation post, and I am indebted to successive commanding officers for such excellent visibility that any failure to recognise facts presented is due to my own defective vision.

Clinical and Laboratory Notes.

A CASE OF VACCINATION WITH MENINGEAL SEQUELÆ.

By Dr. A. Lancet.

The first cases of postvaccinal encephalitis were observed by F. S. van Bouwdijk, Bastiaanse, J. Bijl, and J. T. Terburgh during an epidemic in Holland in 1925. In the following year cases occurred in England, and at about the same time four isolated cases were reported to the Société Médicale des Hôpitaux de Paris by J. Comby, by J. Huber, and by P. Netter, and at Montpellier by Euzière and Pagès. I myself have reported a fatal case[1] of primary vaccination in an infant, and no doubt many have remained unreported. The following case was attended by a colleague in my own district.

An English professional man, aged 34, whose health was generally good, had been vaccinated in infancy and inoculated against typhoid and cholera in adult life. He was revaccinated in London on April 17th, 1929. His wife was vaccinated at the same time, but did not "take." On April 20th, while crossing the Channel, he suffered from headache which increased in severity during the succeeding days, and which became almost intolerable on April 24th. During the nights of April 23rd and 24th he vomited a good deal, and on the 26th I was called in.

His temperature was then 104·5° F., and the pulse-rate 60. The local vaccinal reaction was intense, and he was suffering severe pain in the limbs, the nape of the neck, and the jaws; he said he felt he would go mad with the pain. He suffered from phono- and photo-phobia, and Kernig's sign was pronounced.

A turpentine injection was made in the outer side of the right thigh, and one of pyoformine (Gobey) in the right buttock. The headache diminished on the following day and the pulse-rate increased, while the temperature remained around 102°. On May 1st, a fortnight after vaccination, the temperature fell to 98·6° and there was a tendency to cardiovascular collapse, with syncope and hypotension. This was rapidly relieved by digitalis and adrenalin. On May 6th the blood pressure rose and the headache disappeared completely. The urine became abundant and the patient began to sleep soundly. The abscess, which had evolved slowly, was lanced on May 7th. On May 12th the temperature and blood pressure became normal and the patient felt well.

---

[1] Gaz. Méd. du Nord, Oct. 15th, 1928.

This case appears to be one of vigorous meningitic reaction, appearing early after an apparently successful vaccination. Whether or not it proceeds from the same cause as postvaccinal encephalitis is not known, but it is certainly less serious. E. Frommel and J. Baumgartner[1] have recorded a case of acute meningitis with slight leucocytosis which was cured in ten days. Postvaccinal encephalitis, on the other hand, begins from 10 to 12 days after a normal primary vaccination, usually in the later years of childhood, and half the patients die within ten days. H. M. Turnbull and J. McIntosh[2] have reported seven cases of encephalomyelitis, of which six were fatal. The lesions were quite different from those of encephalitis lethargica and of poliomyelitis, and in three cases inoculations of the brain and spinal cord revealed the presence of vaccinal virus transmissible to rabbits. Turnbull and McIntosh attribute the disease to Jenner's virus, but C. Levaditi ascribes it to a virus similar to that of epidemic encephalitis which happened to be in the patient's body and was only intensified by vaccination. Postvaccinal encephalitis is unknown in Spain, where rabbit neurovaccine is used.

The complication is so rare as to give little cause for alarm; nevertheless certain precautions should be taken. Primary vaccination should be done as early in life as possible. The scarification should be light and the insertions should be two in number and set some distance apart. Congenital debility, diabetes, herpes, and convalescence after influenza or measles should be temporary contra-indications. Finally, the patient should avoid fatigue and risk of infection, and should pay especial attention to nasopharyngeal hygiene.

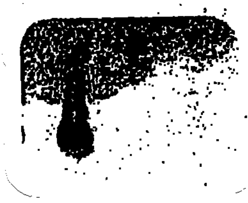
Ardres, Pas de Calais, France.

FACIAL NEURALGIA DUE TO A HIDDEN ROOT.

BY PERCY G. MURDEN.

THE following case appears worthy of record :—

An elderly woman had suffered for many years from neuralgia of the left upper jaw. When interviewed she was very insistent on the degree of suffering she had experienced, and complained of "burning" pains in the area of the third to the eighth teeth on the left side, the sensation extending to the Gasserian ganglion. When asked to open her mouth for examination she protested strongly that she could not do so, but from her manner there seemed little doubt that tact would accomplish the "impossible." This proved correct, and examination showed that the left fourth, sixth, seventh, and eighth teeth were missing, having been extracted (according to the patient) some 20 years previously. The gingiva presented a perfectly healthy appearance, and a thorough search failed to reveal a sinus or localise the pain.



Radiogram showing root embedded in alveolus.

At this stage two facts were clear: the "impossibility" of opening the mouth had proved to be imagination; and no obvious local disease had been found to account for the pain. To have assumed, however, that the pain was also a product of the patient's imagination would have been shirking the issue; for the fear exhibited by the patient—or at least part of it—might be secondary to some other sensation. Consequently an X ray examination was made, which disclosed a root embedded in the alveolus below the floor of the antrum (see figure). The root was subsequently removed, and the patient has since reported that the pain has ceased.

It seems safe to assume that had not the psychological aspect received due consideration the case might have been classified as facial neuralgia with an obscure ætiology and left unrelieved.

London, W.C.

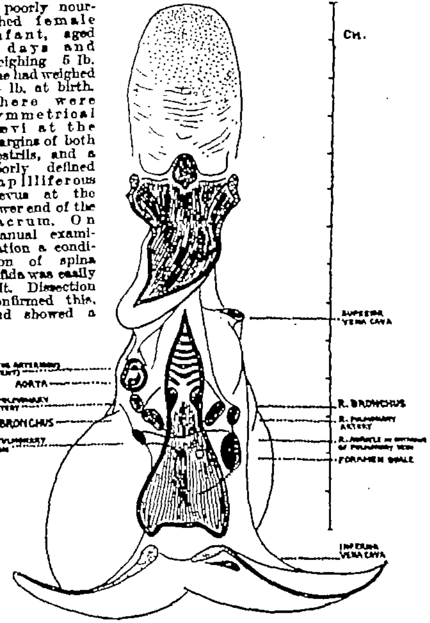
A CASE OF
CONGENITAL ATRESIC ABNORMALITY OF THE ŒSOPHAGUS.

BY T. V. COOPER, M.R.C.S. ENG.,

JUNIOR ASSISTANT PATHOLOGIST, JOHN BURFORD CARLILL LABORATORIES, WESTMINSTER HOSPITAL.

THIS abnormality was found in the body of a child which had died of broncho-pneumonia.

The child was a poorly nourished female infant, aged 4 days and weighing 5 lb. She had weighed 5¼ lb. at birth. There were symmetrical nævi at the margins of both nostrils, and a poorly defined papilliferous nævus at the lower end of the sacrum. On manual examination a condition of spina bifida was easily felt. Dissection confirmed this, and showed a narrow deficiency ¼ inch wide and 3 inches long. The nerves were normal in position. It had been noticed during life that the baby appeared unable to retain food, and when a small rubber catheter was passed into the œsophagus, milk immediately flowed into the postnasal space, causing an acute attack of dyspnœa, and the instrument was obviously not in the stomach. The child had never passed a normal stool, the motions consisting solely of meconium.



The child had been full-time with a normal presentation, but 14 days before labour acute hydramnios had come on, causing the mother to complain of œdema of the legs and shortness of breath. The fœtal parts could not be felt during this last period.

At autopsy the child's stomach contained gas and some greenish fluid, presumably bile. The œsophagus, when followed down from its upper end, terminated in a blind sac ½ inch above the bifurcation of the trachea. There was no apparent continuation of this sac. When followed up from the gastric (cardiac) end, the œsophagus was found to communicate with the trachea at its bifurcation. The lumen appeared of normal dimensions. Both the foramen ovale and the ductus arteriosus were patent, but I omitted to observe specially whether any other cardiovascular abnormality was present. No other congenital abnormalities were detected, but the right lung sank in water and showed several broncho-pneumonic patches, while the left lobe was markedly congested. The liver was toxic, but the spleen and kidneys were normal. The intra-abdominal umbilical cord was widely patent.

---

[1] Schweiz. Med. Woch., 1926, lvi., 857.

[2] Brit. Jour. Exper. Path., 1926, vii., 181; see THE LANCET, 1926, ii., 504.

This type of abnormality has received considerable attention in the past.[1] [2] Sir Arthur Keith and Dr. J. E. Spicer[3] offer the following embryological explanation.

"At the end of the third week the floor of the primitive œsophagus becomes depressed and shows dorsal œsophageal and ventral tracheal divisions. These are demarcated by lateral ridges which meet posteriorly in a crescentic fold. From the caudal end of the tracheal division grow the lung buds. By the end of the fifth week the crescentic fold spreads forward, uniting the two lateral ridges and thus forming the tracheo-œsophageal septum. To produce the abnormality presented in this instance, the lateral ridges and folds, instead of growing horizontally backwards to meet at the junction of the lung buds and œsophagus, thus dividing the primitive œsophagus in two, must grow obliquely backwards and downwards so as to meet on the dorsal wall of the foregut.

I owe my thanks to Mr. Stanley Dodd, under whose care the case was; to Dr. Braxton Hicks, senior pathologist, for permission to publish the case; and to the pathological clerk, Mr. Michael Perkins, for the preparation of the drawing.

BRITISH MEDICAL ASSOCIATION.

ANNUAL MEETING IN MANCHESTER.

(Continued from p. 559.)

SECTION OF DISEASES OF CHILDREN.

UNDER the presidency of Dr. PAGET LAPAGE (Manchester) a discussion on

TUBERCULOSIS IN EARLY CHILDHOOD

was opened by Dr. CHARLES MCNEIL (Edinburgh), who began by paying tribute to the lasting value of Pirquet's work. The subject, he said, was not only wide and complicated, but also well worn; it was, however, of first-rate importance for all who had the medical care of children. He would confine his survey to the first five years of life, a period which in 1927 gave a much greater number of deaths than the later period of childhood and puberty. There were four chief clinical types—viz., meningeal, respiratory, abdominal, and the general or disseminated type; these were responsible for 95 per cent. of the tuberculosis deaths at this age. Meningitis easily took first place; in England and Wales the deaths from tuberculous meningitis were three times greater than those from pulmonary and abdominal tuberculosis. It was a common remark that the Pirquet test often failed in tuberculous meningitis and in general tuberculosis, but this was not so if the test were properly performed. In the first two years a positive tuberculin test was of great value in diagnosis and of grave significance because at this period latent or healed tuberculosis was a rare event and active tuberculosis was generally fatal. In later childhood a positive test was of less value in diagnosis, but a negative test was of great value in excluding tuberculous disease, although it had to be remembered that the test might, if rarely, fail to appear in an actually tuberculous condition.

The existence of healed or dormant tuberculous lesions was an important fact in later childhood, but in the first two years of life tuberculous infection nearly always proceeded to tuberculous disease, and in the great majority of cases the lesions were in the abdominal mesenteric glands. The practical conclusion from clinical and post-mortem evidence was that latent tuberculosis could scarcely be said to occur in infancy and was uncommon in the later years of the period of survey. Tuberculous meningitis, so common and so deadly in the first years of life, was only the end-result of an earlier focus of disease implanted in the body; it was a secondary and not a primary type. In an analysis of 51 fatal cases the pulmonary glands were the seat of the primary lesion in 33, the abdominal glands in 10, and the cervical glands in only 2 cases. The value of post-mortem examination in tuberculous meningitis could hardly be exaggerated in revealing the situation of the primary focus, and in the majority of cases this was a thoracic lesion. Of pulmonary tuberculosis there were four types—tuberculous bronchitis becoming broncho-pneumonia; acute caseous pneumonia with or without acute cavity formation; chronic fibroid pneumonia with cavities; and a caseous tuberculous process at the hilum of the lung, spreading into it. The first two types occurred at an age when simple bronchitis and pneumonia were common conditions, and they gave the same physical signs. Some clinical features were helpful in distinguishing the tuberculous condition; the illness was insidious in its onset and quiet in its course, but presently there was definite weakness, pallor, and loss of flesh. The X ray picture in tuberculous broncho-pneumonia was, of course, unmistakable. As to the third type, even at an early age pulmonary tuberculosis might be a relatively slow process, lasting for many months. The fourth type was more difficult to diagnose than any other, as there were only the general signs of a severe progressive toxæmia. One of the most interesting things about abdominal tuberculosis was the variation in its frequency in different towns and districts of the British Isles. In early childhood primary abdominal tuberculosis was a milk infection. A high death-rate and case-incidence of abdominal tuberculosis in any area were, therefore, a reliable index of widespread infection of the milk-supply with tubercle bacilli.

It was, said Dr. McNeil, hardly necessary to emphasise the greater importance of preventive as against curative treatment of tuberculosis at any time of life, and this was certainly true of the first period, where in some of its clinical types the number of deaths equalled the number of cases. The old heresy that tuberculosis was a hereditary disease, fatally transmitted from parents to children, still lingered in the minds of many and blinded them to the real dangers. The problem of milk in relation to tuberculosis in young children was complicated. Until all our dairy cattle were free of tubercle there were two ways of dealing with the situation: pasteurisation or boiling. It was a settled custom to boil our eggs; there was far more reason to boil our milk. The key to the problem of prevention of pulmonary tuberculosis in childhood lay in the early detection of cases of phthisis in the middle period of life, in their isolation, in their instruction in hygiene, and above all in the reduction of their numbers. The segregation of young children from tuberculous parents and insanitary homes, as in the Grancher system in France, was not feasible as a general policy; in the few cases where it was practicable it was, of course, the most effective safeguard.

Discussion.

Dr. H. THURSFIELD (London) confined his remarks to the clinical diagnosis of intrathoracic tuberculosis at two periods in childhood—viz., up to the third or fourth years of life and during school age. Below two years of age the diagnosis was extremely difficult between a chronic slowly resolving broncho-pneumonia, a tuberculous broncho-pneumonia, and a localised empyema. It was in such cases that the Pirquet and Mantoux tests were untrustworthy. The points on which to rely in diagnosis were a positive family history, the discovery of a palpable spleen, enlargement of the lymphatic glands of the thoracic wall, and lung puncture in all doubtful cases. In children of school age the diagnosis of a frank pulmonary lesion was as easy as in an adult, but pulmonary or intrathoracic tuberculosis was diagnosed a great deal too freely. The greatest importance should be attached to direct contact with a known tuberculous subject and but little importance to a history of chronic cough, unless associated with failure in general health. A physical sign of importance was persistent loss of movement at one or other apex. X rays were not an aid in early invasion of the lung. A subcutaneous tuberculin test was of great value in a suspected case when the temperature was running evenly. In such cases a general or focal reaction was decisive.

Dr. J. M. SHELLIE (Birmingham) gave statistics from the Birmingham Children's Hospital which showed that in 15 per cent. of the autopsies over a seven-year period death was due to tuberculosis. In 33 per cent. of these the mediastinal glands were the seat of the primary lesion, in another 31 per cent. both the mediastinal and mesenteric glands were involved. It was reasonable to deduce, therefore, that two-thirds of the fatal cases in Birmingham were due to infection with human tubercle bacilli. To find healed tuberculous lesions in children under five years of age dying from other diseases was so exceptional as to be wellnigh negligible. Whilst an appreciable reduction in the death-rate had been obtained by present methods, it was doubtful if they would produce any further reduction. If advances were to be made in its prevention they must be made along other paths. To protect infants and young children from all contact with tubercle bacilli, even if this were possible, would not appear to be the wisest course, as it would but store up added troubles for the periods of later childhood and puberty. For prophylactic purposes it was generally agreed that tuberculin was of no value. Whilst Calmette's "B.C.G." vaccine had been in use for some years, much more detailed information was necessary before his claims could be accepted. In the meantime, discontinuity of infection could be obtained by removing children for a time from all tuberculous environment and from tuberculous milk, and was extremely beneficial.

Dr. STANLEY MELVILLE (London) regarded pulmonary tuberculosis as primarily an affection of the lung parenchyma. It was true that the primary focus might be so small as to defy detection, but the enlargement of the lymph nodes was a secondary stage. The following types of pulmonary tuberculosis were recognised as giving definite radiological evidence: (1) primary acute broncho-pneumonia (infantile phthisis); (2) miliary tuberculosis; (3) the adult chronic indurative type; and (4) hilum tuberculosis—the word hilum being used in a topographical sense, and not conveying any suggestion as to the pathological process which was present. A small primary focus in the lung might produce a secondary mass of glands out of all proportion to the initial lesion. Lack of recognition of this fact had allowed clinicians and radiologists to be overwhelmed by the size of the shadow in the lung. To regard such shadows as evidence of involvement of the lung root in a tuberculous infiltration was fatal to the rational interpretation of the films.

Dr. HUGH ASHBY (Manchester) said the difficulty of diagnosis lay in the early case of tuberculosis. He had almost given up the cutaneous tests as of no value. Of much more value were the clinical signs and a radiological examination. There should be no hesitation in needling the chest in any doubtful case.

Dr. CATHERINE CHISHOLM (Manchester) gave the results of her investigations into the incidence of tuberculosis in about 3500 cases of children aged 1 to 2 years. In only 50 of these was a definite diagnosis of tuberculosis established, and in 20 per cent. of these there was a family history of active disease. She urged that pasteurisation or sterilisation of milk was imperative at present, but tuberculous-free herds were the ideal.

Dr. E. A. SAUNDERS (London) pointed out the extreme value of the collaboration of the clinician and radiologist in diagnosis. Children went through a process of establishing their immunity with a certain disturbance of health. There was a ray of hope in not removing them from all tuberculous contact, but in allowing them to get subminimal doses of infection in order to establish gradually an active immunity.

The PRESIDENT said that recent measures to reduce infection had borne fruit. Apparent healed adult tuberculous lesions might be infectious to children as tuberculosis was very infectious during childhood. Depending on the dosage and severity of the infection, a number of cases in children were curable by fibrosis and calcification.

Prof. C. W. VINING (Leeds) said that a purely localised tuberculous infection did not produce systemic signs of note, and that hilum tuberculosis had been grossly exaggerated as a cause of ill-health. The skin reactions had a negative value, as in suspected tuberculous cases a negative skin test showed that the disease was not due to tuberculous infection. He doubted whether any X ray picture except miliary tuberculosis could be diagnosed as tuberculous. The diagnosis of glands at the hilum of the lung was very difficult and very doubtful.

JOINT MEETING OF THE DERMATOLOGICAL AND RADIOLOGICAL SECTIONS.

X RAY TREATMENT OF THE COMMONER MICROBIC DISEASES OF THE SKIN.

The Joint President, Dr. W. J. S. BYTHELL (Manchester), introduced Dr. J. B. HIGGINS (Salford), who gave the opening address. He said that the progress of X ray treatment in dermatology might be divided into three eras. In the very early days results seemed miraculous. Later some mishaps and a few disasters brought X ray treatment into discredit. Study of the effect of X rays upon the skin, improved apparatus, and means of estimating dosage, had eventually made X rays one of the most reliable therapeutic agents in dermatology. Dr. Higgins proposed to discuss briefly the methods employed in the Manchester and Salford Hospital for Diseases of the Skin in treating the commoner microbic diseases. He said that when X rays were absorbed by the skin certain changes took place in the cells. Hertwig had stated that the secondary rays produced molecular changes in the colloidal albumins. Packard had presupposed enzymes controlling cell activity, which were stimulated by small doses of X rays. Large doses caused inhibition or even destruction of the life of the cell. Holzknecht's theory was that the effects of X rays were due to early changes which preceded injury, and to the suspension of inhibitory influences. Whichever view was adopted it was accepted that small doses of X rays had a stimulating effect in certain skin diseases, notably acne vulgaris. The essential factor was that diseased cells had a greater sensitivity and an effective dose could be given to them without injuring the normal surrounding skin. If hyperæmia was present, however, the surrounding skin was not normal, and there was a narrower margin between stimulation of diseased cells and injury to the hyperæmic area.

By the term "commoner microbic diseases" Dr. Higgins meant acne vulgaris (and indurata), sycosis vulgaris, paronychia, and furunculosis (including carbuncles).

In *acne* X ray treatment was now the method of choice, although it was not indispensable. The apparatus employed by Dr. Higgins produced a collection of soft and medium rays, and the erythema dose was estimated by the Sabouraud pastille. A preliminary course of three or four half skin doses (unfiltered) at weekly intervals was followed by a similar course employing a filter (of 0·5 mm.) of aluminium. In a series of 31 consecutive cases of acne of the face there were no actual failures, though the results in 4 cases were indefinite, and in 9 cases of generalised acne the results in 2 cases were indefinite and one failed to respond. Dr. Higgins cited other methods adopted by various workers. Comparison of the total dosages administered shows that their skin dosage was roughly equivalent to those used in his practice. But no attempt to standardise the dose should be made for the actual absorption varied. Blonde skin absorbed X rays more readily that did more pigmented skin. The shorter the interval between treatments the more cumulative would be the effects. It was supposed that the curative action of X rays in acne was due to the stimulating effects of fractional doses of X rays. There seemed no doubt that there was no direct bactericidal action. It required 120 skin doses to kill a culture of *B. coli* and *staphylococci* (Kloverkorn, 1925). Dr. Higgins had found that doses up to eight skin doses actually stimulate the growth of staphylococci.

The treatment of *sycosis* was peculiarly difficult. It was almost invariably accompanied by hyperæmia, which was the vital factor in deciding upon the X ray dosage. The skin was hypersensitive according to the degree of hyperæmia. The three available methods of treatment, namely, (1) epilation, (2) stimulation of the affected cells, or (3) a combination of the two, must be applied according to the merits of the individual case. General guiding principles were, first, not to treat the acutely inflamed skin seen in mixed infections before the hyperæmia had been reduced. Even then not more than one-third skin dose at weekly intervals could be used. Secondly, with moderate hyperæmia not more than half skin doses could be used. If there was no hyperæmia the dose might be carried to the point of epilation, with effective results. In a series of 30 cases of sycosis 10 received epilating doses and 9 were cured. No filters were used in the treatment of these cases. Probably a filter of 0·5 mm. of aluminium would allow rather larger doses to be used without ill-effects.

Super soft rays had been employed in the treatment of skin diseases by J. J. Eller (1927). Using specially constructed apparatus he found that the phenomena of erythema, pigmentation, and cumulative effects from successive doses corresponded with those of harder rays, but that erythema appeared almost instantaneously (in two or three hours, or less). The penetration was less, and therefore after erythema doses, or even ulceration, healing took place without permanent effects (after fifteen months). The results in acne treatment were not better than those obtained with harder rays, but good results were reported in sycosis, paronychia, and carbuncles.

Discussion.

Dr. **Douglas Webster** (London) expressed interest in the theory, with which he did not agree, that the effect of X rays depended upon the total dosage, five to six skin doses being required to cure acne. He had found ten weekly applications of one-sixth skin doses quite as efficient, and some workers used only one-fiftieth erythema doses. He pointed out that excellent results in lupus had been obtained with high-voltage irradiations and radium, so that the worker need not limit himself to softer X rays.

Dr. **Frederick Gardiner** (Edinburgh) said that the dermatologist, though he need not be a radiologist, should have adequate X ray training. He considered X ray treatment in acne only an adjunct to constitutional treatment. He believed in smaller doses—that is, three doses of one-third skin dose at ten-day intervals. Six months of treatment brought the risk of telangiectases. Regarding sycosis, he did not believe in epilation by X rays, which have a deleterious effect on the skin.

Dr. **Richard Connell** (Carlisle) also regarded X rays only as an adjunct in acne treatment. Microbes could not be destroyed by X rays, except indirectly.

Dr. **Haldin Davies** (London) pointed out that mild cases were not seen by the radiologists who were, therefore, pessimistic. Cases varied enormously in degree and ease of treatment. He emphasised the necessity of constitutional treatment. He usually applied two half pastille doses at an interval of a fortnight in cases of acne. For sycosis he preferred several small doses, avoiding erythema.

Dr E. **Hunt** (Liverpool) also emphasised the need for constitutional treatment.

Dr. **Ferguson Smith** (Glasgow) considered X rays the method of choice in the treatment of acne vulgaris. Personally he did not believe in such large doses, and did not exceed two skin doses per annum, unfiltered. He used doses of one-fifth pastille weekly, with a maximum of 12 doses. His results were brilliant. In sycosis he considered an epilation dose necessary. In treating boils, especially local, he had found a single pastille dose (with temporary atrophy of the gland) better than any efforts to destroy the microbes.

Dr. **William Dyson** (Manchester) believed in small repeated doses for acne. With regard to sycosis, he condemned the use of X rays in acute inflammatory conditions of skin, on account of the risk of atrophy, telangiectases, and epithelioma. He used fomentations first, and X ray treatment after the discharge had ceased.

Dr. G. H. **Lancashire** (Manchester) pointed out the possibility that under-exposure might be responsible for disappointing results.

Reply.

Dr. **Higgins** pointed out that all we can observe after stimulating doses is the clinical effect. We cannot state dogmatically that one-fiftieth or one-third of a pastille dose is the best stimulating dose. With reference to Dr. Lancashire's observation he had often seen patients who had previously had a course of treatment without any effect having been obtained. He did not imply that X rays alone constituted the method of choice, but X rays added to other methods of treatment. There must be coöperation between the dermatologist and the radiologist. The actual dosage used by him for epilation was three half pastille doses at weekly intervals, unfiltered, followed after three to four weeks by another dose using 0·5 mm. aluminium filter. Sometimes after one dose a mild erythema followed in about three days; in this event treatment would be discontinued for three months and recommenced with the filter.

Dr. **Lancashire** then took the chair. He traced the growth of X ray therapy in skin diseases from the time, some 28 years ago, when Schiff and Freund founded the method which had become an indispensable part of a dermatologist's equipment. He then read the following paper on the

X Ray Treatment of Wounds,

contributed by Prof. **Leopold Freund**. Prof. Freund wrote that the older radiologists had found not only that malignant and chronic infective ulcers healed more rapidly under the influence of X rays, but also sluggish and badly healing wounds. Sunlight and powerful artificial light had similar effects. Whether the effect of X rays upon wounds was one of stimulation of healing, or of destruction of a factor inimical to cicatrisation, was of less importance than the fact that small doses were of admitted benefit in badly healing wounds. Prof. Freund discussed one particular indication of X ray treatment, that of fresh and open wounds. Since 1898 he had noticed the curative value of X rays on keloids, and later he had observed histologically that in keloids the hyperplasia of connective tissue commenced in numerous young round and spindle cells around blood-vessels. It had occurred to him that to irradiate these young and particularly sensitive cells might prevent keloid. Since then, after excision of tumours in persons predisposed to keloid, he had irradiated the wounds without stitching or skin graft, using small X ray doses. The results were uniformally good, and the method had been employed in other conditions such as patches of lupus vulgaris, epitheliomata, rodent ulcers, keloids, and pigmented nævi. The advantages of this method over X rays used alone were, first, that X rays had not to penetrate the thickness of the lesion before reaching its base; secondly, if any traces of the disease were left, they were reached more directly by subsequent irradiation than if the wound had been stitched; thirdly, if local recurrences appeared they broke through the thin delicate scar more easily than if the wound had been stitched or skin-grafted. Such wounds, often thick and œdematous, sometimes prevented the recurrences from breaking through and thus delayed the recognition of their presence. The cosmetic results were excellent, and the scars as good as those obtained with Finsen light. In lupus vulgaris and malignant growths the period of irradiation was considerably shortened and over-radiation is avoided. The method was unsuitable where there was movement of the unstitched skin edges, for instance near joints or folds of skin, unless movement was prevented by firm bandaging. Wounds up to the diameter of about 10 cm. had resulted in perfect scars. The duration of healing appeared to be unaltered, and in animal experiments an irradiated wound healed slightly earlier than a control wound not irradiated. The dose used was about 6 to 7 Holzknecht units (H) applied at 6 or 7 sittings at intervals of two or three days. Unfiltered rays of 6 to 7 Wehnelt units (W) hardness are used. A contra-indication to the method was the situation of wounds near folds or angles of the skin. Prof. Freund did not recommend application of X rays before excision, because skin which had been recently X rayed sometimes reacted to every form of trauma with an X ray dermatitis. He quoted Richard Sparmann's statement that in Malays, who were liable to keloid formation, prophylactic irradiation before operation, or irradiation of closed operation wounds, was often useless.

Discussion.

Prof. M. **HAUDEK** (Vienna) agreed that results were better without the use of filters. He recalled good results in the early days before filters were used. He thought one should not regard Dr. Freund's dosage of 6 to 7 H as a set rule.

Dr. **FERGUSON SMITH** (Glasgow) said he had no experience of Prof. Freund's method of treating lupus. His method was to scrape the area, apply liq. hydrarg. nit. and irradiate three to four days later, using one application of X rays, though divided doses might be better. Comparison with non-irradiated patches showed definite benefit.

Sir **NORMAN WALKER** (Edinburgh) referred briefly to his experiences with X ray therapy. He hoped that closer coöperation between dermatologists and radiologists would bring to bear the experiences of both.

Dr. L. A. **ROWDEN** (Leeds) said that he did not believe in coöperation between radiologist and dermatologist. The dermatologist should do his own radiology and then the radiologist could not be blamed for occasional bad results. He pointed out that keloid following amputation of the breast was entirely prevented by X radiation. He did not advocate filters in dermatological cases.

Dr. **DYSON** said that quality and penetration of rays were much more important than the methods of application. Before the correct dosage could be prescribed we must know more of the exact action of X rays on cell metabolism.

The **PRESIDENT** suggested that there might be a return, in a modified manner, to the treatment of lupus by X rays, incorporating Prof. Freund's method. He still used the erosion method extensively, followed by local caustics. It would probably be of advantage to treat the clear granulating wounds, after separation of the sloughs, by exposure to X rays on the lines advocated by Prof. Freund. He had already tried the plan in two recent cases with promising results.

SECTION OF OTO-RHINO-LARYNGOLOGY.

Dr. **WELLS P. EAGLETON** (Newark, New Jersey) opened a discussion on the

CEREBRO-SPINAL FLUID AS AN AID TO DIAGNOSIS AND TREATMENT OF INFLAMMATORY INTRACRANIAL LESIONS.

Referring briefly to the arrangement of the primitive central nervous system, he went on to remind his audience that in mammals, including man, the mesh of the arachnoid mater grows out from the arterial system of the brain. Knowledge of that system enabled them therefore to construct a surgical map of the arachnoid and of the basal cisternæ. Where nerves left the cranium they carried a prolongation of the arachnoid as a fine tubular investment. So fine were the spaces of that system that they would retain the smallest concrete particles, though permeable to fluids. Any inflammation travelling along the nerves caused a reaction in this fine tube and completely obliterated it, shutting off the infected area from the basal cisternæ. But when we left the base of the brain there was no longer a system of large arachnoid spaces but a very fine network. Over the vertex we were concerned mainly with venous transmission of infection. The intracranial veins might be divided into the extradural veins and the venous sinuses, both of which had a dense fibrous coat; on the other hand, the cerebral veins had no outer coat, the place of which was supplied by prolongations of the arachnoid. Any inflammation involving these veins immediately involved the arachnoid. This explained the extreme virulence of intracranial complications of throat infections, which are borne by blood to the cavernous sinus. The clinical picture was not that of meningitis, but began with delirium and proved rapidly fatal. The problem of vertex meningitis was therefore that of the veins, while basal meningitis was concerned with the cisternæ. The arachnoid was part of the general protective mechanism of the body, a low-grade connective tissue. On infection, a rapid proliferation of cells occurred.

The cerebro-spinal fluid was entirely derived from the blood from all the vessels in the arachnoid, not from the choroid plexus alone. The latter did secrete chloride into the fluid, the chloride content of which was higher than that of the blood. The glucose content, however, was identical with that of the blood. In addition, the cerebro-spinal fluid contained a lytic ferment capable of digesting dead brain tissue, a fact that could be demonstrated in vitro. This process accounted for the pyrexia and convulsions that might occur following brain injury, and the presence of a toxin in the circulation (derived thus from the cerebro-spinal fluid) could be demonstrated by injecting the serum of a patient into an animal, producing convulsions in the latter. The cells found in the cerebro-spinal fluid were derived entirely from the arachnoid.

Points in Interpretation.—In interpreting the results of lumbar puncture in an inflammatory case he relied on the following points. Increase of pressure indicated irritation of the arachnoid. Disappearance of glucose meant that it had been consumed by bacteria. Diminution of the chlorides was of the gravest significance, and meant that the barrier between fluid and blood was breaking down. Increase of globulin indicated degeneration of brain cells. A yellow fluid was found when the blood was becoming disorganised and should be considered a presage of impending death. The site of a possible lesion should also be considered. For example, an effusion of blood in the posterior fossa produced all the symptoms of meningitis, with pyrexia and head retraction; in the anterior fossa it produced no signs unless it was large. Loculation might occur in inflammatory lesions, especially of the frontal region, and should be regarded as Nature's attempt to wall off the disease.

Diagnostic Points.—Papillœdema indicated one of three things: venous obstruction, renal disease, or interference with return flow of cerebro-spinal fluid. It was thus often a sign of cerebral abscess. The otologist had several diagnostic tests to assist him. Absence of a response on caloric stimulation of the labyrinth when the head was upright (a normal response being found in the supine position) was an early sign of increasing intracranial pressure. Absence of reaction in all positions was of grave significance in meningitis, unless due to disease of the labyrinth itself. An effusion of blood in the posterior fossa produced a permanent diminution of the reaction to rotation, a point of great medico-legal importance. If there were infection of the frontal area the fluid from a lumbar puncture might be quite normal. The infection was then localised in the subdural space. In the middle fossa no local accumulation of cerebro-spinal fluid occurred, the infection passing directly into the brain; except that in fracture cases a loculation similar to that seen in the frontal region might be found. In the posterior fossa the arachnoid was divided into two compartments by the brain stem; a local collection of fluid in the posterior compartment might lead to sudden death, especially if lumbar puncture were done. Other symptoms of localising importance were the euphoria and mental changes seen with frontal lesions. If the middle fossa were involved there was pain from affection of the fifth nerve, and characteristic indentations of the visual field. When the posterior fossa was infected one saw the basal cisterna complex—pain behind the eye, attacks of stiff neck of varying duration, external rectus paralysis, contraction of the visual fields, and a semi-comatose condition.

Treatment.—Referring briefly to treatment, Dr. Eagleton expressed his belief that the proper course was to remove the primary focus of infection, and to evacuate any localised collections of infected cerebro-spinal fluid. In addition, he ligated the common carotid artery of the same side; this was fairly safe if done under local anæsthesia and if the eye was continually under observation during the operation. He did not regard continuous irrigation of the spinal spaces as a practical measure; it did no good, and might do great harm. Nor was anything effected by injecting drugs into the theca. In order to be at all disinfectant they had to be at a strength which instantly killed nervous tissue. He had recently experimented with intracarotid injections of mercurochrome.

The Significance of Variations in the Cerebro-spinal Fluid.

Dr. J. G. GREENFIELD (London) said that the point of greatest importance was whether the infection of the meninges was local or general. The cerebro-spinal fluid might vary from normal to that indicative of generalised septic meningitis. Reduction of chlorides he considered to be due to a septicæmia, and not to indicate damage to the meninges. Glucose examination he thought of no great value in this class of case. Increase of protein with a normal cell-count indicated a chronic cerebral abscess and was due to œdema of the brain and not to meningeal changes. A high proportion of protein to cells was unusual with a localised meningitis only. A turbid but sterile fluid with normal chlorides and perhaps only intracellular cocci indicated a localised meningitis, and the prognosis was not necessarily bad.

Dr. H. COHEN (Liverpool) stressed the importance of the chemistry of the cerebro-spinal fluid. He did not attach great importance to a diminution in chlorides alone, which was usual with any profound toxæmia. But in generalised meningitis the chemical constituents of the fluid tended to approximate to those of the blood. When therefore uric acid and phosphates of the fluid rose, and the chloride content fell, the outlook was bad. The significance of cells and of bacteria was less; thus with a cerebral abscess there might be many polymorph cells but the chemistry was normal, since the meninges were undamaged, and the prognosis might be good. He did not agree that there was any encephalolytic ferment in the normal cerebro-spinal fluid. Dead brain would autolyse in saline. But disintegration of brain tissue did alter the fluid in one important way—viz., it gave a strongly positive Wassermann reaction. This did not indicate syphilis, and knowledge of this point was of the greatest importance from the clinical aspect.

The PRESIDENT spoke of the great value and importance of an early report on the cerebro-spinal fluid in these cases. The examination was made as a matter of routine with all his own cases of this nature as soon as they were admitted to his wards, and the report was thus available at his first visit. So important was it that a resident pathologist had been appointed to the Manchester Royal Infirmary.

Mr. W. MOLLISON (London) read a paper on the

Drug Treatment of Spasmodic Rhinorrhœa.

He had employed thyroid gland for cases associated with pregnancy, and in two such, as well as in others not so associated, had had striking successes. The drug on which he ordinarily relied was calcium, either as the lactate, colloidal, or as kalzana. With the calcium he gave small doses of parathyroid extract. The results he had obtained with all treatment had been very variable. Frequently there was no effect at all, in other cases the treatment was completely successful. Of 40 consecutive cases, 15 were cured, 11 improved, 5 in statu quo, and 9 untraced.

Mr. LINDLEY SEWELL (Manchester) spoke of the importance of a sudden access of cold in bringing on an attack. Thus to get out of bed on to a cold floor might produce one. He had used kalzana. He thought the best results were obtained from a strictly vegetarian diet (excluding even milk, cheese, and eggs), and from sea air. The latter seemed particularly effective if it blew over a wide expanse of sand or mud. Any obstruction in the middle meatus of the nose must be removed.

Dr. J. ADAM (York) referred to the importance of general treatment, and the value of a cold douche after a warm bath in promoting vasomotor tone. He relied little on drugs.

Mr. F. HOLT DIGGLE (Manchester) considered that three factors had to be considered: 1. Endocrine disturbance. Diagnosis was difficult, but a polyglandular treatment was often effectual. 2. Infective. The condition followed an acute infective condition such as appendicitis; such cases were very intractable. 3. Neurotic. Hypopiesia was often the characteristic feature, and cure of the latter relieved the rhinorrhœa.

Mr. T. RITCHIE RODGER (Hull) read a paper on the

Reproach of the Chronic Running Ear.

He pointed out that the principal difficulty arose from the indifference of the general public to the importance of treatment; this indifference was being to some degree diminished by the work of school clinics. Prevention was better than cure; an early paracentesis would in many cases avoid a chronic otorrhœa. If in spite of active treatment, including removal of adenoids, the acute ear continued to discharge, an early resort should be had to mastoid drainage. Aural discharge that continued despite treatment for a month indicated mastoid disease; operation should not be postponed beyond the sixth week. A determined effort was necessary to impress the importance of early, vigorous, and complete treatment.

Mr. H. NORMAN BARNETT (Bath) said that he did not think the treatment afforded by school clinics was very effective. If simple treatment did not rapidly cure otorrhœa, mastoid disease was present. Although in certain cases zinc ionisation gave good results, he urged the importance of early operative measures. It was futile to continue with palliative measures that were not rapidly successful. The Schwartze operation was in most cases all that was needed. It was very safe and gave very good results.

Mr. C. A. SCOTT RIDOUT (Southsea) assigned great importance to early and vigorous treatment. After paracentesis or perforation he did not like to wait beyond three weeks unless the ear was healing, but did a Schwartze operation. That operation was very successful, and offered no bar to recruitment to the public services. He had observed that operation for the otorrhœa following acute fevers was often too long postponed.

Dr. J. ADAM said that he had found that in chronic otorrhœa very frequent lavage was effective. Every two hours the patient's ear was thoroughly syringed by a trained nurse; he had found an enormous improvement in the chronic cases so treated, few proving intractable.

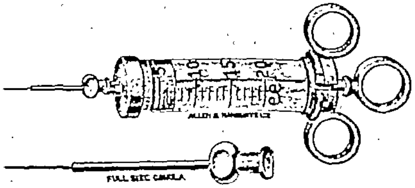
Mr. F. B. GILHESPY (Birmingham) said that he had been impressed by the importance of measles in the ætiology of chronic otorrhœa. In a large series of cases it was the starting-point in 1 in 4, and it had to be remembered that very many children suffered from this disease before school age. Local authorities were very difficult to move in this matter, but quite recently four beds had been assigned in Birmingham for the operative treatment of school-children.

Mr. R. SCOTT STEVENSON (London) had been impressed by the enthusiasm of school authorities, including medical officers, for ionisation. On the other hand, the general body of aural surgeons did not feel it. His own experience with this method was disappointing. Simple cleanliness was sufficient in most cases, and he believed that if the ear was meticulously cleaned it made no difference at all whether it was then ionised. He had tried both treatments in parallel series of cases, and had been forced to this conclusion: nearly all cases cleared up with cleaning alone; the remainder were resistant to ionisation and required operation.

New Inventions.

A VASOTOMY SYRINGE.

IN making an injection into the vas when doing a vasotomy two matters of primary importance in connexion with the cannula used are: (1) its point should be constructed so as to avoid damaging the inner lining membrane of the tube, and (2) the calibre should so fit the lumen of the vas as to prevent, if possible, any leakage out of the vasotomy opening of the fluid being injected. To overcome these difficulties I have had made a syringe, with fine bayonet-fitting and stainless steel cannulæ, which cannot become detached whilst the injection is being given. The cannulæ—made in four calibres, 21, 22, 23, and 24 standard wire gauge—are each mounted in a shaft which forms a shoulder. This shoulder effectually prevents the cannulæ from being inserted too far into the vas, eliminates the possibility of puncturing it lower down, and occludes the remainder of the vasotomy opening.



Messrs. Allen and Hanburys, Ltd., of Wigmore-street, London, are the manufacturers of the syringe.

London, W. J. F. PEART, F.R.C.S.I.

Reviews and Notices of Books.

THE WORK OF MEDICAL WOMEN IN INDIA.

By MARGARET I. BALFOUR, C.B.E., M.B., C.M., late Chief Medical Officer, Women's Medical Service, India; and RUTH YOUNG, M.B.E., B.Sc., M.B., Ch.B., Personal Assistant to the Chief Medical Officer, Women's Medical Service, India, and Lecturer, Lady Hardinge Medical College, Delhi. With a Foreword by Dame MARY SCHARLIEB, D.B.E., J.P., M.D., M.S. London: Humphrey Milford, Oxford University Press. 1929. Pp. 201. 9s.

SOME ten years ago, in connexion with the annual report of the National Association for Supplying Female Aid to the Women of India (Countess of Dufferin's Fund), we took occasion to plead once again for the establishment of a Government service, holding that the task of providing Indian women with adequate medical attention was beyond the power of any unofficial body, however richly subsidised. We expressed the view that with the limited resources at their disposal it would be wiser for the Women's Medical Service to restrict their activities to a narrower field so as to ensure more assistance, better pay, and more adequate equipment for those medical women officers who had undertaken to live and work in India. This criticism brought a reply from Dr. Margaret Balfour, at that time joint secretary to Lady Dufferin's Fund, to which we gladly gave publicity. In this letter she explained the curious difficulties in administration and finance under which the Fund struggled to maintain its position and influence in the absence of complete official recognition. The arguments were impressive. The claim of the Women's Medical Service to a status equal to that of the I.M.S. has always been advocated in our columns, and in our Students' Number the conditions of the Service receive annual recognition. Dr. Balfour became Chief Medical Officer of the Service in 1920, retiring some years later only to return to India for research work on maternal mortality. She has now from her unrivalled experience both inside and outside the Service, and with the collaboration of Dr. Ruth Young, produced a book on the work of medical women in India which demands serious study. It is now nearly 60 years since the first medical woman landed in India. Most of the earlier pioneers have died; some of them survive but no longer do active work. It is right that the new generation of medical women should realise the efforts and achievements of their predecessors in order that their enthusiasm for future developments may be kindled and that their criticism of present conditions may not be too severe. *Dr. Balfour and her collaborator* survey the field of work and briefly explain the purdah system and those problems of caste and racial custom which make the need of medical women in India greater than in any other land. Admittedly the greatest handicap to the advancement of Indian women in any direction is their lack of education. The Indian woman, according to the authors, is not "groaning for release from the purdah or pining for the blessings of education. . . . The reason for pressing reform and education is not so much the happiness of individuals, but the improvement of the whole standard of Indian life by enabling women's influence to permeate society." A chapter is devoted to the praise of famous women and of others whose names have escaped recognition in Europe. The steps whereby the Countess of Dufferin's Fund has expanded into the Women's Medical Service for India are set out; the work of women medical missionaries is discussed and also the conditions of private practice. The history of medical education of women in India is briefly outlined. The figures for 1928 show that 253 women students were studying for a University course in India last year, 121 in the Lady Hardinge Medical College for Women only, and 132 distributed in the mixed medical schools of Madras (63), Bombay

(50), Calcutta (18), and Lucknow (1). In addition there were 5 taking a course for certified practitioners (apothecaries) and 445 studying to become sub-assistant surgeons. The last part of the book is taken up by a discussion of the present position of preventive medicine in India and of miscellaneous activities in which medical women have been concerned; three short appendices respectively on maternal mortality, infant mortality, and early motherhood show how difficult it is to collect accurate statistics in India.

The authors have given a balanced presentation of the work of medical women in India, past and present, and have set out their ideas of its future needs. It would be unfair to summarise still further the closely written argument in which the direction of future development favoured by these experienced workers are outlined. It should be studied alike by the enthusiasts and the sceptics among those concerned with the provision of medical aid to the women of India.

LABORATORY METHODS.

1. *Die Laboratoriums-Methoden der Wiener Kliniken.* Herausgegeben von H. K. BARRENSCHEIN und R. WILLHEIM. Leipzig: Franz Deuticke. 1928. Pp. 800. M.44.

2. *Clinical Laboratory Procedures.* By GEORGE L. ROHDENBURG, M.D., Director of the Laboratories, Lenox Hill Hospital, New York. New York: The Macmillan Company. Pp. 266. 14s.

3. *Laboratory Manual of the Massachusetts General Hospital.* Second edition. By ROY R. WHEELER, M.D., and F. T. HUNTER, M.D. Philadelphia: Lea and Febiger. 1929. Pp. 101. $1.75.

1. ATTEMPTS to include the whole field of modern laboratory technique in one volume will soon have to be abandoned since the essence of these books must be a detailed account of technique. There are very few methods of investigation, whether in biochemistry, bacteriology, serology, or hæmatology, which have escaped attention from Dr. Barrenschein and his colleague, although pressure on the space has cut down many descriptions to an absolute minimum. On the other hand, room has been found for mention of the snags which await the investigator, and the arrangement of the book is admirable. Certain inclusions and exclusions are surprising. The serological diagnosis of tumours is given great prominence, with many alternative methods. So is the laboratory diagnosis of pregnancy, including even a reference to extra-uterine pregnancy. And there is a chapter on cinematography and photomicrography. Among the omissions we note the serological diagnosis of hydatid disease, the skin reactions of asthma, and the complement-deviation test for gonorrhœa. Little help is given in the search for *Entamœba histolytica*, and the cyst illustrated is not characteristic. No references to fuller descriptions of methods are supplied. But most laboratory workers will find a use for this book, if their duties take them off their beaten track.

2. In his preface Dr. Rohdenburg states that this is a collection of laboratory methods which in his hands have shown their relative simplicity and clinical accuracy over a period of years. No claim is made for originality, free use having been made of all current text-books. The selection only of those methods of which the author has personal experience prevents the perpetuation of errors, but it is doubtful whether this is a valuable addition to the vast library of works on clinical pathology of trans-Atlantic origin. Unlike most of its fellows it has no illustrations; in so far as this saves space it is an advantage, but the advantage has been counterbalanced by the insertion of blank pages. In theory such blank pages are meant for notes; in practice they serve the young and zealous for the collection of an interesting series of samples of reagents, most of which are soon forgotten. Viewed in later years these bring back memories of happy student days as nothing else can, and occasionally supply a triumphant solution to a problem. Rarely, however, will any worker make a useful private collection that fills up more than a fraction of the space here provided.

3. The book by Dr. Wheeler and Dr. Hunter, unlike many of its kind, gives a good deal more than it promises. Only the first three chapters are devoted to laboratory technique, and though they are adequate they contain nothing beyond what can be found in most manuals of clinical pathology. The remaining three chapters, however, deal with special diagnostic procedures, therapeutic technique, and prophylactic measures, and are mainly concerned with work at the bedside. Here is assembled material hitherto available only in a scattered form in various books and papers. The technique of such procedures as the liver function test by phenoltetrabromphthalein, the Dick test, duodenal intubation, blood transfusion, cisternal puncture, and a host of others is clearly described. These three chapters are really valuable and should be of great service to the hospital resident and to the pathologist with clinical interests.

LES ACCIDENTS DE LA CHOLÉCYSTECTOMIE.

By SERGE HUARD, Ancien interne des Hôpitaux de Paris. Paris: Masson et Cie. 1929. Pp. 116. Fr.16.

THIS is a good review of the dangers of cholecystectomy. The anatomy of the bile-passages and hepatic artery is elaborated with all the variations which have been described. The author's contention is that irregularities are common enough to render hazardous the classical methods of removing the gall-bladder, and that the patient's safety depends rather upon the skill of the surgeon than the suitability of the technique. A new method for cholecystectomy is described of which the essential features are the separation of the gall-bladder from the liver first in the middle of its length; then those structures in the gastro-hepatic omentum which are liable to injury are pushed backwards and to the left without being exposed to view. There is nothing radically new in the procedure, which has only been performed in six cases. There is an interesting résumé of reported examples of injury to the ducts or artery.

GYNECOLOGY.

Fourth edition. By WILLIAM P. GRAVES, A.B., M.D., F.A.C.S., Professor of Gynecology at Harvard Medical School; Surgeon-in-Chief to the Free Hospital for Women, Brookline. London: W. B. Saunders Company. Pp. 1016. 48s.

IN this country we have learned to regard the frequent appearance of weighty and encyclopædic tomes as a characteristic feature of American medicine. Yet each new edition awakens fresh wonder at both the reproductive and the absorptive powers of our professional brethren in the United States.

The volume is divided into three parts. The first part, representing about one-fifth of the whole, is taken up with physiology and the relationship of gynæcology to the general organism. The section on the physiology of the uterus and ovaries is excellent so far as it goes and has been brought up to date by the inclusion of recent work on the menstrual cycle and the functions of the corpus luteum. The separation of obstetrics from gynæcology, customary in America, makes the attempt to discuss the physiology of these organs apart from their reproductive functions appear illogical. The relation of gynæcology to the breasts, skin, and to the digestive, circulatory, nervous, and other systems is also discussed only in so far as menstruation and disease in the reproductive tract are concerned, not from the wider aspect of its relation to the reproductive function as a whole.

Part 2 covers the diseases of the reproductive tract classified on a pathological basis. Inflammation is considered under the two headings of special inflammatory processes, almost wholly devoted to gonorrhœa and tuberculosis, and general inflammatory processes, *in which an anatomical arrangement is adopted* and the infections of the various portions of the reproductive apparatus are described together with those of the urinary tract and pelvic portions of the bowel. In our view no adequate perspective of the infections of the reproductive organs can be obtained, if due consideration is not given to those arising from the reproductive process itself. Here the venereal infections appear to have undue prominence, whilst post-partum and post-abortum infections do not receive attention commensurate with the part they play in the causation of pelvic infections. Such conditions as chronic metritis and chronic subinvolution are dismissed with less discussion than is warranted by their clinical importance. New growths are exhaustively treated and well-illustrated, and the other aspects of gynæcology receive their fair share of attention.

Part 3 on operative gynæcology takes up about a third of the pages. Here a full account of the details of surgical procedures is given and this forms the most distinctive feature of the book. It is profusely and clearly illustrated—so much so that many of the operations seem simpler and easier than they will be found to be in practice.

THE SCIENCE OF CHARACTER.

By LUDWIG KLAGES. Translated from the sixth German edition by W. R. JOHNSON, B.A. London: Geo. Allen and Unwin, Ltd. 1929. Pp. 308. 10s. 6d.

GERMANY seems to welcome an occasional revolt against the narrow confines of the professorial world; an extreme example is the movement for "Schools of Wisdom," associated with Prof. Count von Keyserling. Ludwig Klages is also known for his unconventional educational ventures, but has not gone so far from the beaten track. Apart from the somewhat sweeping cultural vision which takes all knowledge to be its province, the author's approach to the study of character is not unorthodox; but unlike most recent observers, Dr. Klages uses the static method. Modern psychological approaches to the genesis of character traits are concerned with finding the processes at work. Dr. Klages takes up the older standpoint and describes character, character traits, and peculiarities making for disorder. It must be admitted that he does this very well, with a culture and equipment that more fertile minds might envy.

SPEECH AND HEARING.

By HARVEY FLETCHER, Ph.D., Acoustical Research Director to the Bell Telephone Laboratories. London: Macmillan and Co. 1929. Pp. 331. 21s.

THE art of analysing and accurately measuring electrical currents, and the characteristics of mechanically vibrating systems, having reached an advanced stage of development, it became apparent some 15 years ago to the Bell Telephone System that great advantages would accrue from a similar analysis of speech and hearing, to enable their technicians to engineer their instruments with greater intelligence. This investigation has been proceeding ever since at their research laboratories; a considerable part of the effort has been devoted to securing devices which would convert sound waves into electrical form and back again with the least possible distortion, and out of these researches have come large and unexpected returns in the application of such devices to gramophones, to radio reception, and to apparatus for testing defects of hearing. Dr. Harvey Fletcher has embodied the results of these researches in a large and interesting work of which Part I. is concerned with the mechanism of speech and the characteristics of speech-waves, Part II. with the physical properties of music and noise, Part III. with hearing, its mechanism, limits of audition, and means of testing, and Part IV. with the perception of speech and music, the recognition of pitch, the effects of distortion, and kindred matters. That section of the book which deals with hearing is the most interesting to the medical man. On the theories of audition, Dr. Fletcher states his conviction that the evidence is overwhelmingly in favour of an extension of the theory originally proposed by Helmholtz, the modifications being introduced by our greater knowledge of the mechanics of the cochlea, and particularly of the effects of "loading" of the fibres of the basilar membrane by the surrounding fluid on the lines suggested by G. Wilkinson and A. A. Gray. The excellent description of various types of audiometer has a special interest, for there is little doubt that these instruments will be in general use by otologists in the near future. A very interesting form is one to be used for testing large groups to find those whose hearing is deficient for speech; the instrument is of a gramophone type in which the sounds gradually decrease in intensity; these sounds are conveyed by electric wires to receivers in the ears of those to be tested, who write down what they hear as in a dictation lesson. It was tried in a public school in New York City; 40 pupils could be tested at a time, and about 100 in an hour. There are also valuable tables for correlating the results of tests by tuning-fork, watch, speech, and audiometer.

The book is full of detail, and, though the many mathematical formulæ make somewhat stiff reading, could hardly be improved upon.

PSYCHOLOGY.

The Health of the Mind. By J. R. REES, M.D., Deputy Director of the Tavistock-square Clinic. London: Faber and Faber, Ltd. 1929. Pp. 201. 6s.

AMONGST the books on Modern Psychology for the use of the intelligent layman, this little volume ought to take a worthy place. The author starts from the neurological approach to bodily mechanisms—considering particularly the conditioned reflex and the endocrine glands. The influence of mind on body and of body on mind is dealt with in a separate chapter. This topic, however, cannot be discussed very deeply in a popular book, and the philosophic pitfalls are left uncovered. The rest of the book deals with psychological mechanisms, mental breakdown, and the problems of adolescence and childhood. The explanations brought forward are substantially based upon the discoveries of Freud, whom the author does not follow into the deepest recesses. However, the book illustrates both in vocabulary and in interpretation the indebtedness which all psychotherapists must admit to Freud and his school. The author gilds the pill, and makes what to many layman would have been a nightmare as recently as ten years ago a clear and adequate explanation of mental distress and failure.

The A B C of Psychology. By C. K. OGDEN, Magdalene College, Cambridge. London: Kegan Paul, Trench, Trübner and Co., Ltd. 1929. Pp. 270. 6s.

WE have learnt to expect learning combined with liveliness in anything from Mr. Ogden's pen. This book does not disappoint us, for his exposition has a freshness surprising in a text-book. In fact this volume is not a text-book in the strict sense of the word, but is an introduction to a subject which has already been departmentalised to an alarming degree. The book begins with a terse definition of the basic terminology, and in the text that follows additional terms are fully defined. Mr. Ogden's linguistic theories give a refreshing bias to his view of the body-mind problem, and his account of nervous mechanisms associated with mind is coloured by the work of Pieron and Watson. In his concise note on psychopathology he gives Freud the credit due to a discoverer and a pioneer without slavish acquiescence in the detail of psycho-analytic theory. In the last 20 pages a number of psychological oddments, such as mental aspects of facial asymmetry, calculating boys, and musical prodigies are touched upon. In short, the author has his little fling before closing the book, and leaves the reader well entertained and disposed for more serious reading in psychology.

RADIUM IN CANCER.

The Conquest of Cancer by Radium and Other Methods. By DANIEL THOMAS QUIGLEY, M.D., F.A.C.S. Philadelphia: F. A. Davis Company. 1929. Pp. 439. $6.00.

THIS book contains the results of 15 years experience in the treatment of new growths by radium, together with a summary of the ætiology and pathology of the disease and an account of the uses of radium in non-cancerous conditions. The author has many good things to say and it is to be regretted that he has not succeeded in saying them more effectively. Particularly wholesome is his insistence on the necessity for diagnosing and treating cancer in its initial and curable stages, attention having been too much concentrated on the late stages of the disease. Dr. Quigley's manner of writing is confused and verbose, although he makes many dogmatic statements on subjects in which dogma is least justified. He complains that in his country the medical profession has not educated itself in the knowledge of cancer and that the treatment has consequently gravitated largely into the hands of quacks. He therefore advocates the concentration within the profession of all the scientific knowledge necessary to control the disease. But it may be doubted if the cause of science is advanced by the statement that the origin of tumour growth "cannot be other than the presence of low grade micro-organisms." The statement is entirely undocumented, as is every other statement in the book.

The time is not yet ripe for this kind of book, even if it had been better written. Precise information, which is here withheld, can alone decide the issue between radium and radical surgery, so that this book is useless to those who are seriously interested and misleading for the general or ill-informed reader. The volume contains 334 illustrations, some of which are good.

Reports and Analytical Records.

THE GERMICIDAL ACTION OF LISTERINE ANTISEPTIC.

(MANUFACTURERS: THE LAMBERT PHARMACAL CO., ST. LOUIS, MO., U.S.A. DISTRIBUTORS FOR GREAT BRITAIN AND IRELAND: S. MAW SON AND SONS, ALDERSGATE-STREET, LONDON, E.C.1.)

THE manufacturers of Listerine Antiseptic asked that their product might be examined for germicidal action by the methods described by their chief bacteriologist, Dr. George F. Reddish (formerly associate professor of bacteriology in the Medical College of Virginia, U.S.A.). Dr. Reddish has contributed many papers to the American journals on the subject of germicidal values and their determination and, as a result of the study of the action of phenol on newly isolated strains of various organisms, has suggested "standards" by which such organisms as *Staphylococcus aureus* and streptococci may be judged, in order that strains of equal resistance to antiseptics may be recognised and used in testing any unknown antiseptic preparation. For the purpose of the experiments here recorded, organisms conforming to the standards suggested by Dr. Reddish have been isolated and used. The culture medium has been prepared according to the formulæ given in the papers referred to, and the technique laid down by Dr. Reddish has been followed very closely.

The tests were conducted with *Staphylococcus aureus, Streptococcus hæmolyticus* and *viridans*, pneumococcus, and *Bacillus acidophilus* odontolycus types I. and II.

1. *Determination of the "Killing Time."*

The technique employed for the first test consisted of adding 0·5 c.cm. of a suitable broth culture of the organisms to be tested to 5 c.cm. of Listerine at 37° C. Subcultures were made with a large platinum loop into 5 c.cm. quantities of a broth suited to the growth of the organism. Owing to the short time required for the death of the organisms several separate experiments were necessary to find an exact end-point. In each case the very slightest growth, visible at the end of 48 hours, was confirmed by streaking some of the broth suspension on to agar. The *majority* of the organisms present were actually killed therefore in much less time than that recorded.

Staphylococcus aureus	20	seconds
Streptococcus hæmolyticus	20	,,
Streptococcus viridans	15	,,
Pneumococcus	10	,,
Bac. acidophilus odontolycus type I.	20	,,
Bac. acidophilus odontolycus type II.	20	,,

2. *The Number of Organisms Killed.*

Using the same strains of organisms as were used in the first series of tests, plating experiments were carried out to determine the number of organisms killed in 15 seconds at 37° C. The method employed consisted in adding 0·5 c.cm. of broth culture of the organisms under test to 5 c.cm. of undiluted Listerine: 1 c.cm. of the mixture was then diluted with 99 c.cm. of sterile saline at the end of 15 seconds. Subsequent dilutions were carried out in order that 1 c.cm. of a final dilution might produce a suitable number of colonies when added to 15 c.cm. of melted agar (temperature 55° C.) and cultured at 37° C. in a Petri dish. The colonies developing in 48 hours were counted, using a Pake's disc for the purpose. Control cultures, made by substituting 5 c.cm. of sterile saline for the 5 c.cm. of antiseptic, showed the number of *viable* organisms present in the 0·5 c.cm. of culture used for the tests. In this way an exact estimate of the number of organisms *actually killed* was obtained. The average result obtained from three estimations in each case was recorded:—

	Millions of organisms killed in 16 seconds at 37° C.
Staphylococcus aureus	612
Streptococcus hæmolyticus	650
Streptococcus viridans	720
Pneumococcus	More than 800
Bac. acidophilus odontolycus type I. ..	640
Bac. acidophilus odontolycus type II. ..	606

3. *Experiments on Serous Membranes.*

By means of animal experiments, whereby the effects of injecting the antiseptic into the various body cavities was studied by killing the animals after the lapse of varying periods of time, the antiseptic was proved to be perfectly safe for use in all the body cavities.

4. *Conclusions.*

1. The statement of the manufacturers in regard to the killing times of various organisms is substantially correct.

2. The actual number of micro-organisms killed in 15 seconds by the undiluted antiseptic exceeds that claimed by the manufacturers; over 600 millions were found to be killed in the 15 seconds time limit compared with the 200 millions mentioned by the makers.

3. The antiseptic has been proved to be perfectly safe for use in all the body cavities.

THE LANCET.

LONDON: SATURDAY, SEPTEMBER 21, 1929.

DIETARY PRINCIPLES IN TUBERCULOSIS.

EVER since OTTO WALTHER issued his challenge at Nordrach to the digestive capacity of phthisical patients, dietetic methods have continued to take a leading place in the treatment of tuberculosis. It was in a way of speaking the first example of a serious attempt to deal with a deficiency disease. But this was all before the science of nutrition had properly arisen. The tragic lessons of underfeeding and starvation seen in Europe during and after the war have taught the vital importance of fats in bodily health, the subtle distinctions in quality of proteins and their constituent amino-acids, the influence of vitamins upon disease and the resistance to infection. The incidence of tuberculosis in particular has shown itself to be profoundly affected by such factors, and attention is turning from the mere sum-total of nourishment required to its nature and exact composition. Work at present being carried on in some continental clinics, notably in Munich and Berlin, has provoked a considerable interest in the German press, both medical and lay. This work has arisen from principles which may be shortly recapitulated, though it must be admitted that upon many points our knowledge is still far from complete. Inorganic salts in a diet, through their influence upon metabolism, and particularly upon water metabolism, are capable of affecting, either adversely or favourably, bodily processes in disease. The liability to infection is closely allied to the water-content of the tissues, as is seen in the poor resistance shown by œdematous tissues, and the latter is largely dependent upon the mineral constituents of the diet. Restriction of sodium chloride may lead to removal of water from the body, and it is possible that variations in mineral salts may in some degree affect the actual reaction of the blood and tissues themselves. Upon the view that the acid-base equilibrium may be shifted to the one side or the other, so may an "alkaline" or an "acid" diet be employed, though upon this subject we are as yet far from fully informed. It is, however, certain that sodium, whether in the form of chloride or carbonate, may act as a water-retainer, whilst such ions as calcium and magnesium are diuretic in action. A drying up of tissues has shown itself to be an essential mode of healing in many so-called exudative conditions, and the value of restriction in fluids and salt has been proved by many in the past and has found particular use in the hands of FINKELSTEIN, STRAUSS, and others in the treatment of eczema and wound infections, and of lupus.

An extension of this principle has now been proposed in the form of a partially salt-free diet for the treatment of other forms of tuberculosis. It originated with Dr. GERSON, of Bielefeld, Westphalia, and attracted the notice of Prof. F. SAUERBRUCH, who instructed his assistant, Dr. A. HERRMANNSDORFER to study Dr. GERSON'S methods and report.[1] A discussion followed before the Berlin Medical Society in July last to which our correspondent there has called attention.[2] Besides the limitation of sodium chloride in the diet, the sole feature to which H. STRAUSS[3] attributes its effect, the Bielefeld workers employ a substitute called mineralogen consisting of a mixture of potassium, calcium, magnesium, and other salts (the exact composition of the mixture does not appear[4]). The diet is, moreover, one in which fresh uncooked food with a high vitamin content is employed as far as possible with a corresponding restriction of carbohydrates. No attempt at over-feeding is made, but phosphorated cod-liver oil is given to the amount of nearly 2 ounces (45 g.) a day. A total energy value of roughly 3000 calories is advised, made up thus: protein, 90 g.; fat, 160 g.; and carbohydrate, 220 g. Protein is thought to lessen the sensitivity to infection, fats and lipoids to raise resistance, whilst carbohydrate excess is said to favour the spread of tuberculous lesions. The diet is thus one of very limited salt and relatively reduced carbohydrate content, in which raw food as far as possible is given, and in no sense one in which increased nourishment *per se* can be the ruling factor. There are obvious practical drawbacks to such a diet, as, for example, its high cost and its somewhat unappetising nature which may make it difficult to overcome the anorexia and idiosyncrasies of tuberculous patients. There is, however, no doubt in the minds of those who have employed it of the value of the diet in lupus. The figures given by HERRMANNSDORFER and others in Germany are impressive, and C. EMERSON has reported favourably from America. Results in bone and glandular tuberculosis seem to offer a definite advance on existing methods of treatment. In phthisis there is at present little unanimity. HERRMANNSDORFER reports definite benefit, and EMERSON in a series of ten cases obtained striking improvement. Others are sceptical and time will show whether hopes have been raised in vain.

Significant is the evidence that over-feeding may be actually harmful in pulmonary tuberculosis. The new testimony that limitation in carbohydrate intake may be beneficial is in accordance with the older experimental work of WEIGERT and with the newer work of E. ANDERSON, FINKELSTEIN, and others. A moderate protein allowance is supported by W. S. MCCANN, C. MARTIN, and others who have found the optimum amount for phthisical patients in bed to lie between 60 and 90 g. per diem. The value of a relatively high fat and lipoid content of the diet is nowhere denied, and a sufficiency of vitamins is clearly important. There is, however, no certain evidence that an excess of vitamins or fat can sensibly aid the body's resistance to tuberculosis. But the influence of mineral salts may well be of vital importance, and the work of STRAUSS, GERSON, SAUERBRUCH, and HERRMANNSDORFER may point the way to a realisation of this fact.

◆

FOOT-AND-MOUTH DISEASE.

EPIZOÖTIC stomatitis has long baffled Ministries of Agriculture and has given rise to political difficulties, national and international. At the Ayr Congress of the National Veterinary Medical Association, to which allusion was made in our last issue (p. 574), a rather more optimistic feeling seemed to prevail regarding the situation in this country. There are several reasons why such a feeling may be justifiable. Our knowledge of the disease has been considerably extended as a result of the last few years of research in this and other countries, much more is now known as to the longevity of the virus in particular circumstances, and this knowledge has pointed to certain probable sources of origin for the initial outbreaks. Further, there is less likelihood nowadays of the widespread escape of infection from an initial outbreak, as happened in 1923, owing to the strengthening of the Veterinary Service of the Ministry of Agriculture. We shall always be exposed to danger from slowness in reporting suspicious outbreaks on the part of the agriculturist, though it is probably true to say that to-day he is better educated in this respect and more alive to his responsibilities. Great Britain can, however, never afford to relax her watchfulness, and there is no better example than foot-and-mouth disease of the futility of a penny-wise pound-foolish policy. The extra expenditure involved in maintaining an efficient and numerically strong veterinary service, and the cost to the country of developing and extending research, are certainly repaid by results several times over. Research into animal diseases not only brings relief to the agriculturist, but it is of benefit to the public health, and for that reason commands the sympathetic attention of the medical profession.

[4] It can be obtained from Pharma, M. Loebinger and Co., Berlin, Wilmersdorfer-Strasse.

Our knowledge of the virus of foot-and-mouth disease has recently undergone a radical change. It was regarded not long ago as a fragile virus outside the animal body, whereas now it is known to be very highly resistant under certain circumstances; for example, it can live for a period of two years when kept chemically dry; it can live for months on just those things which are most likely to result in its being brought into contact with healthy animals, such as hay, straw, bran, and clothing; and it can live for long periods in certain parts of carcasses of animals killed in the incubative or clinically infected stages of the disease provided these carcasses are kept at low temperatures. The virus can only increase in quantity in the body of the living animal, but there it is manufactured in enormous quantity and in amazing concentration in a matter of a few hours. Such is the concentration of virus in the vesicles that fluid from them is still infective in minute dosage when diluted ten million times, which means, as was pointed out at the Congress, that a tablespoonful of such fluid would make 30,000 gallons of infective fluid. In spite of the living body being such a prolific factory for virus production, nevertheless the infected animal's system very quickly purges itself of the virus, so that a few days after full clinical manifestation of disease animals cease to infect their fellows even on close contact. In view of these and kindred facts there would seem to be no reason to assume the existence of farm animals or vermin which act as true carriers of infection. Certain circumstances point to the origin of outbreaks in Britain from virus imported from infected countries in the ordinary course of trade. One such source was discovered a few years ago in undressed pigs' carcasses imported from Holland into Scotland. The possibility of infection reaching us in hay and straw used as packing materials and distributed to farms is beyond dispute, but the fact is very difficult to prove. There is strong reason to believe that some of our initial outbreaks originating in pigs have been due to scraps of chilled beef fed to these animals; indeed, the last two outbreaks in the United States of America have been definitely traced to such scraps of meat sold as pigs' food on shore from ships touching at American ports. We are dependent upon the chilled beef producing countries at present for about 50 per cent. of our meat-supplies, and, as their largest customers, we have every right to ask those countries to control foot-and-mouth disease at least within the premises of the frigorificos, in order to eliminate the very considerable chances of animals being killed for export when in the incubative stages of infection. It is understood that the countries referred to are endeavouring to meet our wishes in this respect, though their task may not be an easy one.

The question of human infection with foot-and-mouth disease was touched upon at the Ayr Congress. It has, of course, long been known that children, like calves, if they drink milk from foot-and-mouth infected cows are liable to develop a fatal enteritis. The losses in calves in this way are considerable in countries where the disease is enzoötic. Cases of supposed foot-and-mouth disease have been reported in adults, but only very rarely, and the diagnosis does not seem to have been supported by experimental proof. An interesting feature of the disease is the existence of three serological types of the virus. An animal can be made to pass through three consecutive attacks of the disease on exposure, in succession, to the three types of virus, and doubtless it is this phenomenon occurring naturally which has led to the belief that the immunity acquired by a natural attack is relatively short as compared with immunity in some of the bacterial diseases. The immunity left by the attack of any one type of virus against reinfection by its own type is now known to last for several months, if not for more than a year.

◆

THE AGE OF MARRIAGE AND OF CONSENT.

AT the fourth session of the Advisory Committee of the League of Nations on Traffic in Women and Protection of Children held at Geneva in May, 1925, it was decided to institute an inquiry into the law relating to the age of consent and the age of marriage. The investigation has since been going on and replies have now been received from 42 countries. These are analysed in a report which was published at Geneva last year.[1] At first sight it would appear a simple task to compare the age of marriage and the age of consent in different States, but the inquiry was evidently not so easy as it might seem. The age of marriage is not absolute. There may be a minimum age not subject to exception; a minimum age under which, in exceptional cases, marriage may take place by dispensation; and an age, generally the age of majority, under which the consent of a third party is necessary. The age of consent is also subject to modification. It may be without exception, or with special provisos, governing for instance offences by juvenile delinquents who are of much the same age as or younger than the victim; again, specially severe penalties may be instituted for offences committed by persons in authority, such as foster-parents, guardians, or medical men. The committee was faced with the difficulty of classifying offences; eventually they decided to consider only cases of indecent offences against a boy or girl.

It does not require much imagination to see that the numerous divergences between the laws of various countries on these matters are not so unreasonable as they might at first appear. The desirability of a rigid minimum age of marriage appears obvious at first sight; but in practice where no exceptions are admitted the marriage age has generally been set very low. The advantage of some elasticity is shown in the fact that the common reason for exceptions, in the States where they are admitted, is the pregnancy of the girl while it also becomes possible to raise the age minimum. The comparative figures in European countries and in the British dominions for the age of marriage are rather surprising. Great Britain, for instance, and Australia, have the low minimum age, not subject to exception, of 14 years for males and 12 for females; South Africa has 12 for females, part of Poland 7 for both males and females. On the other hand, subject to exception, Belgium has 18 and 15 years for males and females respectively, Denmark 21 and 18, Finland 21 and 17, France 18 and 15, and Germany 21 and 16. With regard to the age of consent, too, there are great discrepancies. In Great Britain and most of the Australian provinces it is fixed at 16, without exception, for both sexes, the figure for France being 13, Belgium 16, and Italy 12; while among countries which have an age limit subject to special provisos, in the United States of America this varies between 10 and 18 in the different States; in parts of Czechoslovakia, for both sexes, it is fixed at 14, and in South Africa, for women only, it is 16. The figures are not all strictly comparable, since they are formulated on entirely different bases. In the laws of Eastern countries there is also a marked divergence. In Japan, the marriage age, subject to exception, is 17 for males and 15 for females, and in China 16 for both sexes not subject to exception. The age of consent, not subject to exception, laid down for females only, is 13 in Japan and 12 in China. In Egypt the age neither of marriage (18 for males and 16 for females) nor of consent (14 for both sexes) is subject to exception.

---

[1] Publications of the League of Nations. IV.: Social. 928, IV., 20.

In many countries, however, the minimum age of marriage bears little relation to the lowest age at which marriage actually takes place. In Great Britain, for instance, it must be many years since any marriage of a girl at the age of 12 has been recorded. But in some races, notably in India, a very low age of marriage is still the custom. The Indian press has recently given much publicity to proposals for alterations in legislation for the ages of both marriage and consent. The position in India is complicated, as regards the contraction of marriage, by the necessity of providing for so many different communities. The actual age at which marriage may lawfully be contracted is, except in Christians, undefined, but marriage cannot lawfully be consummated in females under the age of 13. Dr. MARGARET BALFOUR and Dr. RUTH YOUNG in a book reviewed on p. 613 note that the principle on which the Hindu custom of early marriage is founded is that young people of both sexes are likely to lead chaste lives and form lasting affections for each other if brought together early. But they state that the progress of education as well as legislation is tending to discredit early marriage. The age of consent in India (14, or 13 if the girl is married) applies only to females. The revival of interest in the subject in India at the present time may be due partly to Miss MAYO's book "Mother India" and partly to the fact that the committee appointed by Government to consider the age of consent is expected to report shortly. The committee has, we understand, recommended the raising of the age of consent, and has expressed the opinion that a law penalising marriages between parties below certain ages is essential. The need for registration of marriages, which is not at present compulsory, is likely to be emphasised in the report. Meanwhile there are indications that any reasonable strengthening of the existing regulations would receive public support. At a recent meeting of the Social Hygiene Congress in London, Prof. CREW expressed the opinion that there is little or no difference between the age of puberty in the tropics and temperate climates. This view was not contradicted, although it is not in accordance with the general teaching of the past. If it proves to be well founded there can be no good climatic reason for maintaining such pronounced differences in the age of marriage as at present exist in different countries, and the trend of legislation is likely to be in the direction of uniformity at the higher age limits.

Annotations.

"Ne quid nimis."

NOISE.

SOME of our newspapers reproduce each day, from their hundred-year-old files, extracts whose triviality does not prevent their being sometimes more instructive than the records of important events. Thus we learn that the *Times* of Sept. 11th, 1829, reported complaints that officers had seized the horses of a stage-coach in the City and threatened to take them to the green-yard. The Lord Mayor, whose orders were in question, explained that it was his wish to prevent the disturbance of divine service, and that no one who went to church could deny that the noise of the stage-coaches frequently drowned the voice of the clergyman. Earlier references to the nuisance of street noises in London can be found, and residents of what is now the West End once complained bitterly of the bellowing and quacking that accompanied the market methods of the day. It is probable that traffic in our cities is now quiet in comparison with earlier periods, for the noisy impact of iron upon granite has been replaced by the almost silent contact of rubber and wood, though the spasmodic explosions, rattles, and hootings of to-day may be more disturbing than the continuous din of bygone times, and the householder living by a busy traffic route must reconcile himself to sudden onslaughts of rumbling and shaking, which may easily upset his temper and damage his dwelling.

Noise has lately become the subject of vigorous protest, and many ills are attributed to it. A direct effect is to be observed in boiler-makers' deafness, in concussion deafness, and in the temporary loss of hearing caused by exposure to the loud noise of machinery. The inability to converse with ease in a tube train affects alike all people with ordinary powers of hearing, and is accepted as inevitable. A similar inability in proximity to a pneumatic drill is apparently accepted as inevitable by the operator, but calls forth emphatic complaint from victims slightly more remote. Such obvious physical results of noise are not, however, its only offence. Health is said to be affected, and in his annual report for 1928 Dr. C. W. Hutt, medical officer of health for the Borough of Holborn, suggests that the use of the pneumatic drill should be prohibited on the ground of injury to the health of the workmen using it. Evidence of such injury would be a valuable contribution to the subject for, apart from the cases of deafness noted above, demonstrable effects of noise upon health are rare. Workers in noisy trades are not known to suffer from illnesses attributed to noise, and records of its influence upon output do not appear to be available. The Duchess of Bedford, in describing her recent flight to India and back, noted casually that all communications with the pilot had to be carried on in writing; yet the effect of noise upon the health of long-distance aviators is not a problem of importance, nor did anyone anticipate evil results to the contestants from the terrific roar of the machines in the recent Schneider Cup race. The ordinary noises of modern life are trivial when compared with this vibratory assault upon the human frame.

The real mischief of noise is not, then, any demonstrable physical effect upon health. It is unfortunately obvious that too many people—some drivers of commercial vehicles, for example—can endure it with equanimity, so long as they are producing it themselves; but to the busy brain-worker, to the sick, the nervous, or the wakeful, noise is a serious infliction to which adaptation may be impossible, though it is perhaps an unsafe proposition to advance that it can of itself induce nervous troubles. A distracted woman, who recently committed suicide after killing her daughter, left an emotional description of the noises that she declared had so tormented her as to lead to the final tragedy. The description was evidence of a mind that would have grasped at any object upon which to project its inner troubles, but the uncritical publicity given to the case fostered the idea that noise can serve as a primary cause of insanity or suicide—an idea which, in view of the contagiousness of emotional states, would be wisely omitted from anti-noise propaganda. Such arguments are not needed. It is sufficient that many nervous people are peculiarly susceptible to all kinds of stimuli, and they have at least the right to be protected from those unnecessary noises that the ordinary man resents. This resentment may well serve as our standard, for our unsophisticated likes and dislikes are reasonable guides to conduct, and did not, for example, await the progress of science to tell us that butter was a better food than margarine, or fresh air and sunshine healthier than the smoke of the town. We need not wait for scientific proofs of ill-effects from modern din; our desire for peace and quiet is the justifiable foundation of the campaign against noise.

STREPTOCOCCUS IN RHEUMATIC FEVER.

It is perhaps nothing more than a coincidence that the production of highly plausible evidence incriminating the streptococcus in scarlet fever has been followed by a recrudescence of the old theory that rheumatic fever is caused by an analogous organism. There is, however, a considerable difference between the two cases. In scarlet fever there is found a streptococcus which produces an exotoxin which kills rabbits and behaves like other exotoxins. In rheumatic fever a remarkably neutral organism is held responsible; and whatever toxin it produces is certainly of small virulence to animals. Three strains of this organism are discussed in the annual report[1] of the Metropolitan Asylums Board. These are Small's *Streptococcus cardioarthritidis*, Birkhaug's strain, and that of Lazarus-Barlow isolated in England. Dr. Lazarus-Barlow has described in an earlier communication how he extracts from these organisms an endotoxin which, when injected into rabbits, causes a slight rise of temperature and ill-defined lesions. He now relates an attempt to produce antisera to these three strains, and finds the rise in temperature diminished (but not prevented) when it is administered. But the antisera were strictly specific, each to its own strain. He concludes that the lesions produced in no way resemble those of rheumatic fever, and though he considers there is evidence of some endotoxin, this is no more virulent than that obtained from many strains held to be saprophytic. Of exotoxin there is no evidence at all. In a companion paper[2] Dr. N. Gray Hill is unfeignedly sceptical of any advantages following the administration of antisera prepared from these strains in acute rheumatism. Rheumatic fever, he remarks, is a disease running an uncertain and complex course, not to be compared with that of scarlet fever. Improvement following injections needs careful analysis and control, and in the 15 cases he describes he could find no evidence of improvement although serum rash was troublesome. An attempt was made to discover the frequency of occurrence of this type of organism in rheumatic and control cases. Fifty throat swabs in each series were forwarded, unidentified, to Dr. Lazarus-Barlow; 34 per cent. of the rheumatic and 42 per cent. of the control cases showed the organism. During the last three years Dr. J. C. Small, of Philadelphia, has recorded a remarkable series of cases showing the advantages of serum treatment with his specific antisera. The smaller series at Carshalton must be weighed in the balance on the other side of the scale. This series seems to show quite clearly that the incriminated organism is as widely spread among normal as among abnormal children, that it is of small animal virulence, and that evidence of antitoxin formation is scanty. Allowance must be made for variations in technique, but in the main Small's technique was followed by Dr. R. G. White at the Belmont laboratories of the M.A.B.

THE PREVALENCE OF GALL-STONES.

A STATISTICAL review of cholelithiasis, based on a scrutiny of the records of 9531 consecutive autopsies on patients of all ages performed in the General Infirmary at Leeds, is given by Dr. D. M. B. Gross, of the Department of Pathology of the University of Leeds. The basis of this review is the sounder for the fact that an autopsy is made on nearly every patient who dies in the infirmary. Taking the figures, then, as representing some 10,000 unselected individuals it appears that 6 per cent. of all men and 12 per cent. of all women have gall-stones. The age-incidence shown in the charts which Dr. Gross has drawn does not differ materially from what is commonly assumed, except for the demonstration that the solitary cholesterol stone is quite rare until the sixth and seventh decades. An entirely new fact, however, emerges from the statistics in regard to latency. In the 800 autopsies in which cholelithiasis was present the corresponding clinical notes and history gave no suggestion of their presence in 576 cases; in other words, cholelithiasis was latent and symptomless, so far as could be judged from the records, in about three cases out of four. The widely accepted notion that pregnancy contributes to cholelithiasis is negatived by this study; it offers no support to the view that gall-stones are more frequent in married than in single women. The conclusion Dr. Gross draws is that "the factors influencing gall-stone formation are common to both sexes, but more potent in the case of women. In addition to the common factors there is a sexual one, other than pregnancy, acting in women alone." The survey provides confirmation of the current opinion that faceted stones and pigment concretions are associated with cholecystitis, whereas the solitary cholesterol and mulberry stones are not. The association between the "strawberry" gall-bladder and the "mulberry" calculus is established on statistical grounds, apparently for the first time. There appears to be a definite relationship between diabetes and cholelithiasis, and also between atheroma and cholelithiasis. But no association between cholelithiasis—as distinct from cholecystitis—and peptic ulceration can be seen in the data here given.

THE DISCOVERY OF TWO DIFFERENT FORMS OF HYDROGEN.

WITHIN the past two years a discovery of more than ordinary importance was made in Germany, and excited great interest in scientific circles. The discovery consists in the theoretical prediction, followed by the experimental proof, that in ordinary hydrogen gas the molecules are of two kinds instead of being all alike. The new work led to much discussion at the recent meeting of the American Chemical Society at Minneapolis, and thus arose an impression in uninstructed circles that it had its origin in the United States. The discovery does not in any way upset present-day views upon the intimate atomic structure of matter, according to which the ultimate atoms of any element are composed of a positively charged nucleus inside a surrounding shell of negative electrons which annul the central charge. The atom of hydrogen consists of the simplest possible nucleus carrying a simple unit of positive charge, together with one neutralising electron outside. In the atoms of elements other than hydrogen the nucleus itself has a definite structure, being built up of a number of hydrogen nuclei together with a lesser number of electrons intimately welded together by forces whose nature is not yet understood. The electrons and the hydrogen nuclei are the fundamental material out of which other elements have been formed, probably under the extreme conditions of high temperature and pressure existing in the stars. The new work leaves this conception unchanged, because it differentiates not the atoms but the molecules of hydrogen into two kinds. Ordinary hydrogen gas consists of molecules, each molecule being a pair of hydrogen atoms held together by a chemical band in a dumbbell-like structure. According to the system of mechanical principles which has been found in recent years to apply to matter considered on the subatomic scale, there should be two possibilities for the hydrogen molecule; the difference is subtle, but can be indicated by a crude representation of each nucleus as having a spinning motion which obeys the new mechanical principles and not the principles of ordinary mechanics; and the small difference between the two different kinds of hydrogen molecule depends upon whether the two nuclei of a molecule happen to have their spinning motion in the same direction or in opposite directions. This idea of a spinning motion of the nucleus is an addition to the earlier and simpler view in which the hydrogen nucleus was considered merely as a positive electrical charge. The two forms of hydrogen molecule, which have been named by their discoverer, K. F. Bonhoeffer, orthohydrogen and parahydrogen, can be separated at very low temperatures, and have slightly different freezing points and boiling points. Mathematical physicists have for some time been engaged in elaborating new mechanical and electrical principles to account for the ultimate structure and phenomena exhibited by matter. The real importance of the discovery lies in the fact that it confirms the truth of the principles tentatively adopted and gives confidence that the work is being pursued on the right lines.

ALUMINIUM SILICATE IN THE TREATMENT OF GASTRIC ULCER.

THE medical treatment of gastric ulcer in England at the present time is largely confined to dietetic methods combined with the use of various antacid remedies, such as atropine and alkaline salts. It is, however, of interest that bismuth carbonate is still used in large quantities either alone or in conjunction with the magnesias, although it is generally accepted that its virtue as an alkali is almost negligible. In assessing the popularity of bismuth it should be remembered that when originally employed it was chosen not as a neutraliser of acid, but in order to afford protection to the ulcer itself. In small doses this could hardly be achieved, but many physicians were accustomed to give it in considerable quantity in the belief that by settling in the ulcer crater it would assist healing. There is no doubt that when administered in sufficient quantity it is possible for barium and bismuth to remain for long periods in the craters of gastric ulcers; the phenomenon is one which has been observed by countless radiographers, but whether such a local plaster, as it might be called, is of any real therapeutic value is more doubtful. In recent times there has been a tendency in certain European countries, notably in Spain, to make use of aluminium silicate in the treatment of chronic gastric ulcer, and a certain number of successful cases, with X ray evidence of the healing of the ulcer under treatment, have been published[1] by Dr. F. Gallart Monés, of Barcelona. Treatment of these cases consisted chiefly of milk feeds given every three hours with 75 grains of a preparation containing aluminium silicate thrice daily; the results were satisfactory, the ulcer craters disappeared in X ray pictures, and the patients gained steadily in weight. It is a little difficult to decide to what extent the aluminium silicate was responsible for the results in these cases because, according to the author's own statement, alkalis were given in addition when pain was present; but there would appear to be grounds for believing that the substance selected is more suitable for producing a local protective effect than was its predecessor bismuth. The medical treatment of gastric ulcer still presents such difficulties, and the surgical treatment is so far yet from perfection that this new therapeutic suggestion appears worthy of further inquiry.

A POLYVALENT BACTERIOPHAGE.

THE differential diagnosis between cholera and dysentery is not always easy in the early stages, and the increasing use of the bacteriophage in the treatment of both infections has suggested the desirability of the preparation of a polyvalent form of this agent for use in tropical countries. From India, where d'Herelle and Maloine claim to have treated cholera successfully with the bacteriophage, J. Morrison and A. C. Vardon[1] report the production of a bacteriophage having a wide valency amongst different types of dysentery bacilli and strains of cholera vibrios. By combining various strains of bacteriophage, each of which had its activity raised to a maximun, they have built up a polyvalent mixture which they have tested upon a number of cholera and dysentery organisms in order to evaluate its full potentialities. The question whether the bacteriophage thus obtained is to be considered a true mixture of independent strains or a strain which has acquired polyvalent characters is not discussed in their paper. For therapeutic use the different lysing solutions were prepared separately, the bacteriophage being of such strength that the contents of the culture flasks were completely cleared after six hours' incubation. After mixing, the solutions were filtered through Chamberland F candles, and, if sterile, were issued for use. The authors state that a compound bacteriophage prepared in this way was used in two small outbreaks of cholera, comprising 60 cases in all, and that the mortality in treated cases was 20 per cent., against a mortality of 70 per cent. in the untreated cases. With regard to dysentery, they state that the combined bacteriophage is as reliable as the ordinary dysentery bacteriophage, but do not give any details of the results achieved. This paper is a typical example of a number of individual reports, covering relatively small collections of cases, which are appearing at the present time. The value of such reports in creating interest in the possibilities of a new remedy is undoubted, but, as we noted, referring to the observations of Dr. A. Compton in our issue of August 10th, p. 289, it is important to devise clinical experiments with the object of estimating the true place of this agent in therapeutics. The bacteriophage acts only against living and multiplying bacteria. Theoretically it should find conditions very suitable for its activities, especially in cholera, and to a somewhat lesser extent in dysentery. If the bacteriophage will act as a destructive agent of these organisms in vivo, the discovery is of immense importance. Cholera and dysentery take a large toll of human life, and if their specific cure is really in our hands, the fact should be capable of proof in a fashion which will refute all statistical criticism, and comply with the requirements of a properly controlled scientific experiment. It should not be impossible to reduce the variable factors in two extensive and parallel series of cases to a single one—the administration or non-administration of the bacteriophage—and to settle whether under identical conditions this single factor sways the prognosis, and to what extent. Such an investigation is all the more urgently called for, since in the careful laboratory experiments of W. W. C. Topley and his collaborators no protective effect could be shown from the oral administration of the bacteriophage. There is, in the long history of medicine, such a melancholy tale of sovereign remedies, which one after another have fallen into discredit and are forgotten, that we are justified, even in the much abused name of humanity, in asking that the test shall be fairly made before we finally accept any new specific. This Ehrlich did for salvarsan; this Roux, Martin and Chaillaw did for diphtheria antitoxin; and these have stood firm in the "quaking bog of therapeutics." How will it stand with the bacteriophage?

A FREE GIFT OF SPLINTS TO HOSPITALS.

GOVERNMENT contractors have still on their hands a large stock of splints and kindred items which they took over from the Royal Army Medical Corps at the end of the war. They have decided to give these away free of charge to hospitals, infirmaries, cripples' homes and similar institutions rather than hold them over a period of years to meet the slow requirements of the ordinary market. The whole of this stock is new, and although slightly store-soiled is in useful serviceable condition. The following are the principal items:—

Arm splints, wood, Clarke's pattern	85
Wrist splints, dorsiflexed, iron	50
Leg and thigh splints, wood, Liston's pattern, with or without footpiece, in sets of three .. Sets of each	150
Extension apparatus, Guy's pattern, complete with clamp, shot can, pulley, and cord	450
Humerus splints, iron, Le Page pattern	30
Back leg and thigh splints, wood, hinged at knee, with adjustable footpiece	140
Leg splints, iron, Jones's skeleton pattern	45
Arm extension splints, Sinclair's modification of Thomas's knee splint, with swivel ring	2600
Bed cradles, iron, Lawrence's pattern	90

We have no doubt that many hospitals will make haste to avail themselves of this generous offer. All the splints offered are those in routine use, and the opportunity should prove particularly valuable to the smaller hospitals on which the increasing number of motor accidents makes such heavy demands. The Sinclair arm extension splint with swivel ring proved its value in the war, and while it is undoubtedly the best all-round splint for arm cases in bed it is frequently absent from hospital equipments. The Liston splints, while now little used in the ward treatment of fractures, still retain their value as first-aid appliances, and should prove useful to hospitals which have ambulances to bring in accident cases. An illustrated list will be sent post-free on demand by Messrs. A. Fleming and Co. (Surgical Supplies), 39, Victoria-street, London, S.W. 1, and the splints will be packed free of charge and despatched carriage forward. The public-spirited offer merits the gratitude of the hospitals which will benefit by it, and is one, we feel, which might be followed with advantage by other firms.

IRRADIATION AND HEALTH.

THE suggestion made early this year by the Medical Research Council that artificial light may not be an effective agent in all circumstances was founded on the results of controlled observations on school-children and on the irradiation of varicose ulcers. The protocols of two of the investigations which led to the doubts expressed in their annual report for 1928 have now been published,[1] and the public will see how carefully these investigations were planned. The result of one of the experimental studies has already appeared,[2] but without the long table setting out details of each case. The other investigation now recorded in full is that in which a group of 287 school-children were divided into three approximately equal batches, one batch being exposed to light from a naked carbon-arc lamp in doses deemed appropriate, another batch to a similar lamp screened by window glass, while a third batch received no irradiation at all. The weight of each child in the various batches was noted periodically throughout the six months during which the experiment was carried out, and the height at the beginning and end of the period. A daily record of colds and coughs was kept, and of the prevalence of infectious fevers. The occurrence of chilblains (low in all the groups), the progress in school work, the incidence of diseases other than colds, together with the subjective impressions of teachers, parents, and the medical officer were also noted. Unfavourable symptoms attributed to treatment were rare and trivial. All these results, when carefully collated, gave no clear indication that either type of irradiation had produced either harmful or beneficial effects. In a prefatory note to this report the Medical Research Council make it clear that these investigations are only a part of a many-sided programme of study, and that the results of the particular inquiries here recorded supply answers only to the precise questions which Dr. Colebrook chose or was able to put. It would be legitimate for anybody to criticise her report on the grounds that she used the wrong kinds of rays, applied them too long or too briefly, at intervals too long or too short, but only provided that he can produce valid evidence that some kind of radiation applied under conditions obtainable in the wholesale treatment of school-children has a beneficial effect demonstrable under conditions as critically controlled as those of Dr. Colebrook's experiment. Until this has been done it is proper to doubt whether light treatment under such conditions will have any real benefit, and, further, whether the greater incidence of minor ailments among school-children in an urban area during the winter months is due in any significant degree to deficiency of light.

ACCLIMATISATION.

THE people of Jacobabad live in July under an average temperature of 98° F., or two degrees below blood heat, whilst in certain inhabited parts of Siberia the midwinter temperature is 60° F. below zero. Though much can be done to protect the body from such extremes, notably by creating artificial climates inside clothes or walls, a good deal of physical adaptation is required by those who greatly change their environment. This acclimatisation, always a fascinating study, has lately found a commentator in Sir Aldo Castellani, who has compiled a mass of valuable information into a short paper,[1] well illustrating both his practical knowledge and his original outlook. One of his maps shows that human energy is highest in Western Europe and the United States, and lowest in South America and South Africa. In the tropics much, of course, depends on humidity, and it has been found that the temperature of a normal man suitably clothed can be regulated so as to remain within normal limits with a high air temperature provided the humidity is low. Haldane found that there was no abnormal rise of temperature till the wet bulb indicated 88° F., provided the experimenters were stripped to the waist or clad in light flannel. If, however, the wet bulb exceeded this temperature by even a degree, then the body temperature rose hour by hour in proportion to the rise of the wet bulb above 88° F. With this abnormal rise of temperature there was an increase of the pulse-rate of about twenty beats per minute for every degree Fahrenheit. When Europeans first enter the tropics there is an increase of pulmonary capacity, but this is only temporary, and possibly due to the diminished quantity of blood which has been diverted to the congested skin and liver. No change is noted in the pulse-rate of the majority of normal Europeans on entering the tropics; the blood pressure is usually lowered. A tropical climate per se, says Sir Aldo, does not cause true anæmia; indeed in a series of observations made by Kop there was no difference in the blood of people in temperate and tropical climates. After discussing climatic effects on the digestive and urinary systems, and on endocrine metabolism, he passes on to the effects of pressure, and some of the local winds of the tropics. A further interesting section, on the rays of the sun, contains résumés of experimental work in connexion with the absorption and properties of these rays from the point of view of tropical medicine, and after some consideration of chronic skin irritation and of pigmentation the paper concludes with practical hints on clothing.

[1] Irradiation and Health. Two Experimental Studies by Dora Colebrook, M.D., B.S.Lond. 1929. Special Report Series. H.M. Stationery Office. Pp. 47. 1s. 6d.

[2] THE LANCET, 1928, i., 904.

[1] Reprinted from the Jour. Trop. Med. and Hyg., July 1st and 15th, 1929.

The section on the effects of heat contains useful information on the various ways of taking temperatures. Sir Aldo says that if a temperature reading in the axilla is to correspond with a reading in the mouth the axilla must be dry; in the tropics there may be several degrees difference between axilla and mouth. Pembrey and Nicol point out that the temperature in the mouth is apt to vary considerably, and that it is not reliable in cold weather or after exercise, and Haldane has found that it varies greatly in different people. In warm and moist air the mouth temperature approaches the rectal. The reason why the oral temperature is lower than the rectal is said to be that in cold air the proximity of the skin, and possibly the nasal cavity as well, has a cooling effect, whereas in warm air there is no such difference. In India, Crombie found in 15 careful observations that the mouth temperature was on the average 0·22° F. below that of the rectum, whereas Pembrey found the difference as much as 1·50° F. during cold weather in England. As regards the time the thermometer should remain in the mouth when taking temperatures, Sir Aldo considers that if nothing hot or cold has lately been placed in the mouth, and it has been kept closed for a short time, two to three minutes should suffice. In his experimental work in India, Crombie found that to get accurate results ten minutes were necessary in the well closed and dry axilla, eight minutes in the mouth, and three or four minutes in the rectum.

THE TECHNIQUE OF BIRTH CONTROL.

IN a recent correspondence in the *Times* about the low birth-rate attention was drawn by Father Francis Woodlock, S.J., to the fact that fewest children occur in families whose eugenic value is highest, because the parents of those families practise birth control. "Don't blame Nature" writes Father Woodlock, "but give the Devil his due." This letter evoked a reply from Lord Dawson of Penn who, while urging the desirability of adequate parenthood for the well-being of husbands, wives, families, and the community, denied that the practice of contraception was necessarily diabolical. Few people, however, would deny that birth control, as practised in the community to-day, acts on the whole dysgenically. While the existing contraceptive methods are practicable by the better educated classes, they are ill-adapted to the use of unintelligent and improvident couples, or couples in which either partner drinks. Of all the psychological characteristics which are likely to promote fertility in England to-day, there is probably none more potent than habitual drunkenness. If the self-possession necessary to the taking of contraceptive precautions at the appropriate moment is lacking in either husband or wife an enhanced fertility will result. The dysgenic effects of contraception to-day are therefore intimately related to the problem of drunkenness in the slums. If these dysgenic effects are to be abolished, it is essential that a harmless and reliable contraceptive method should be discovered which will ensure a continuous period of sterility for a minimum of several weeks at a time, and which will demand no forethought on the part of wife or husband.

Such a method is practised in the clinics of Johann Ferch, in Austria. Another and quite different method was described by Dr. Ernst Gräfenberg and Dr. Norman Haire at the Third International Congress of the World League for Sexual Reform, which met in London last week. The method consists in the insertion into the body of the uterus of a small silver spiral ring which is left in situ for a year. Dr. Gräfenberg laid stress on the difference between his method and those involving the insertion of foreign bodies into the cervical canal, by which ascending infections are facilitated. He claims that he has used his method upon over 1100 women, that as long as the genital tract is healthy when the coil is inserted sepsis never ensues, and that sterility is never caused. In fact, the coil has several times been inserted as a treatment for sterility, and the woman conceived after its removal. According to Dr. Gräfenberg, the endometrium has but one response to mechanical stimulation—namely, hypertrophy. The hypertrophy caused by the coil is such that the fertilised ovum is incapable of embedding itself and conception cannot take place. Though this hypertrophied endometrium is shed at each menstruum neither menorrhagia nor dysmenorrhœa is caused. The coil never embeds itself in the uterine wall, and the incidence of neoplasia is no greater in his series than in the normal. The theoretical considerations which underlie Dr. Gräfenberg's method do not commend themselves to orthodox medical opinion in this country. Nevertheless, his paper was keenly discussed at the conference, and deserves the most impartial consideration. Dr. Haire also drew attention to this method in his paper. He pointed out that the Russian observers believe that its efficacy depends on a physico-chemical change which prevents fertilisation of the ovum. In his opinion it might well be that the Russian view and Dr. Gräfenberg's view were both correct.

Further evidence as to the practicability of the use of existing contraceptive methods by proletarian women has been submitted at a medical conference held on July 10th at the invitation of the North Kensington Women's Welfare Centre. Brief reports in response to a questionaire were submitted by medical officers from nine birth control clinics throughout the country and the following resolution was passed. "This conference . . of medical officers of birth control clinics . . . considers that a regular examination with a speculum is essential before a method of conception control is recommended; and it urges the committees of such clinics to afford facilities to their medical officers to make this examination." As one of the medical officers present said, the speculum examination makes the difference between a scientific and a philanthropic approach to contraception. Follow-up systems are by no means universally in use at these clinics, so that it is difficult to appraise the practicability of the methods advised. A significant note, however, is made by Dr. Kathleen Slim, of Wolverhampton, who says that "50 per cent. of women that were fitted with Dumas pessaries were advised by the doctor to use soluble pessaries also, and one box was given with the initial outfit. With two exceptions no one has renewed the supply." At Wolverhampton also Semori tablets were used in cases in which patients had a pronounced objection to using a rubber pessary. Semori is a froth-producing substance, made in Germany, for which powerful germicidal powers are claimed. It was too soon, however, for an opinion to be given as to the results. Though the patients are asked at their first visit to return after a week and then every six months, all the clinics appear to lose touch with a number of them.

So far as they go, the figures submitted at this conference support the conclusion of Mr. Norman Himes, who made a careful statistical survey of British birth control clinics in 1927. This conclusion was that the methods then taught were not satisfactorily practicable by the least desirable elements of the population, whose fertility is most burdensome to the State. The importance of discovering a really reliable contraceptive, which is also harmless and fool-proof, will therefore be grasped by everyone who shares Father Woodlock's sociological in contrast to his theological opinions.

Opening of the Medical Schools.

IN connexion with the opening of the session at the London Medical Schools, the following arrangements are announced:—

Charing Cross Hospital.—The prizegiving will be held at the hospital at 4.30 P.M. on Oct. 5th. The annual dinner will be held at 7 for 7.30 P.M. at Gatti's Restaurant, Strand, Dr. J. M. H. MacLeod presiding.

Guy's Hospital.—The formal opening of the winter session will take place on Oct. 1st at 3 P.M. at the hospital, when Sir Humphry Rolleston will deliver an address on Medical Societies as Educational Factors. The treasurer of the hospital, Mr. F. P. Whitbread, will preside.

King's College Hospital.—The opening of the centenary session will take place at the Medical School, Denmark Hill, London, S.E., on Oct. 2nd, at 2.30 P.M. Lord Gorell will preside, and Sir Gregory Foster will deliver the introductory address.

London Hospital.—The annual dinner will be held at the Mayfair Hotel on Oct. 17th at 7.30 for 8 P.M., Mr. Hugh Lett presiding.

Royal Free Hospital.—The inaugural address on the Return of Woman to Medicine will be given on Oct. 1st, at 3 P.M., by Dr. Jane Walker, who will present the prizes for the session 1928–29.

St. Bartholomew's Hospital.—The annual old students' dinner will be held in the Great Hall of the hospital on Oct. 1st, at 7 for 7.30 P.M., Sir Frederick Andrewes, F.R.S., presiding.

St. George's Hospital.—The annual prize distribution will take place in the board room of the hospital on Oct. 1st at 3 P.M., when an inaugural address entitled Doctor and Patient will be delivered by Dr. Edmund Spriggs. The annual dinner will be held at the Hyde Park Hotel, Knightsbridge, on the same day at 7.15 for 7.45 P.M., Dr. D. Cotes-Preedy, K.C., presiding.

St. Mary's Hospital.—The annual dinner will be held at the Trocadero Restaurant on Oct. 4th at 7 P.M., Sir John Broadbent presiding. The annual post-graduate course, of which a detailed programme will shortly be available, will begin on the same day, and will be continued during Oct. 5th and 6th.

St. Thomas's Hospital.—The old students' dinner will be held at St. Thomas's House, Lambeth Palace-road, at 8 P.M., on Oct. 4th. Dr. H. G. Turney will preside.

Middlesex Hospital.—Dr. E. A. Cockayne will deliver an introductory address entitled Life's Endless Chain at Queen's Hall, Langham-place, W., on Tuesday, Oct. 1st, at 3 P.M. Mr. Samuel A. Courtauld, vice-president of the hospital, will preside and will distribute the prizes gained during the past year. The wards, medical school, and research department will be open for inspection after the ceremony; also the new west wing of the hospital, which is now nearly ready for occupation. On the same evening, at 7.30 P.M., the annual dinner will be held at the Savoy Hotel, Mr. A. E. Webb-Johnson presiding.

University College Hospital.—The annual dinner of past and present students will be held at the Hotel Cecil on Oct. 25th, at 7.30 P.M. The chair will be taken by Dr. E. A. Barton.

Westminster Hospital.—The inaugural address will be delivered in the board room of the hospital at 3 P.M. on Oct. 1st by Dr. F. N. K. Menzies. The subject will be the Future Relationship of Public Authorities to the Voluntary Hospitals. The annual dinner of past and present students will take place at Grosvenor House, Park-lane, on Oct. 1st, at 7 for 7.30 P.M., Mr. Stanley Dodd presiding.

Pharmaceutical Society of Great Britain.—The inaugural address of the 88th session of the School of Pharmacy will be given on Wednesday, Oct. 2nd, at 3 P.M., by Dr. Henry H. Rusby, professor of materia medica in the College of Pharmacy, New York University.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

XLIV.

INTERPRETATION OF THE WASSERMANN REACTION IN ADULTS.

PART I.*—INDICATIONS, METHODS, AND NOTATION.

No test in clinical pathology has been more abused than the Wassermann reaction, but its value is becoming more and more recognised, and its employment consequently increased. Few realise the prevalence of syphilis in our adult population—10 per cent. would probably be a conservative estimate.

Indications for a Wassermann Test.

The indications for submitting a patient's blood to the W.R. are: (1) absolute; (2) relative.

(1) *Absolute.*—(*a*) Cases where syphilis is definitely diagnosed—by finding the *Tp. pallidum* or otherwise.

(*b*) All chancres and abrasions of the genital organs following illicit sexual intercourse. In all cases of suspicious sores where the *Tp. pallidum* cannot be found, the blood, if negative, should be tested weekly for at least six weeks, unless a positive result is obtained earlier.

(*c*) The presence of a rash which does not conform to any non-syphilitic skin lesion, with or without history of possible infection.

(*d*) Chronic swellings, ulcers, gummata, aneurysms, and cerebral tumours where syphilis cannot be absolutely excluded.

(*e*) Cases where the symptoms and signs point to a diagnosis of G.P.I. or tabes.

(*f*) Cases where syphilis is suspected or a risk of contracting it has been run.

(2) *Relative.*—(*a*) All cases of chronic ailments which do not respond to appropriate treatment.

(*b*) Patients showing myocardial weakness, especially if under 60 years of age.

(*c*) In angina pectoris, especially if occurring before the age of 40.

(*d*) All cases of gonorrhœa. (The patient may have contracted syphilis at the same time, and have an intra-urethral chancre.)

In this connexion it is important to remember that syphilis may simulate almost any chronic disease, and syphilis of a viscus may produce symptoms and signs of a failure of that organ to perform its normal functions as, for example, in diabetes, nephritis, cirrhosis of the liver. It may be pointed out here, though it will be discussed more fully later, that a positive W.R. does not necessarily mean that all or any of the symptoms are due to syphilis, whilst a negative (especially an isolated test) does not exclude syphilis.

The Choice of Methods.

Much of the odium cast upon the W.R. has been due to the large number of modifications of the original test employed by different workers, and to the fact that the carrying out of the test is frequently delegated to insufficiently skilled workers, often unqualified laboratory assistants. Stokes[1] says: "Few laboratory procedures involve more variables and factors known and unknown than the W.R. Not only do the reagents employed vary in strength so that they must be repeatedly and frequently titrated to determine their activity, but every step must be subject to control, and may vary under the most unsuspected influences. It goes without saying that a high degree of technical accuracy in the handling of the reagents is essential, and this part of the work cannot be entrusted to inexperienced technicians with satisfactory results."

---

* Part II., on Positive Results, will appear next week.

[1] Modern Clinical Syphilology, W. B. Saunders Company, 1926.

The W.R. should mean a test carried out more or less in accordance with the original technique, using inactivated patient's serum, serum containing fresh complement, "antigen," red corpuscles, and hæmolytic amboceptor; these should be derived from *different* sources and a separate hæmolytic system should be used. Since the reaction is a quantitative one the titre of the reagents ought, within practicable limits, to be accurately known. Many of the methods employed are "short cut" ones—e.g., making use of the natural complement present in every fresh serum or of the natural antisheep hæmolytic amboceptor—but since the titre of these substances is not known the results are not always reliable. Admittedly many of these "short cut" methods are more sensitive than the original, but in view of the risk of non-specific results they should be used as complementary to, not in place of, the original method. They may be useful also for estimating the effect of treatment or as criteria of cure rather than for diagnostic purposes.

Four reliable methods of carrying out the original reaction are described and recommended for official use by the Medical Research Council,[1] and of these the most generally performed is No. 1 method, by which many tens of thousands of tests were performed before, during, and immediately following the war at Rochester Row Military Hospital, where they were carefully checked from the clinical side. Moreover, this test gave the most satisfactory results of all the methods of performing the W.R. discussed at the recent International Congress at Copenhagen.

The Wassermann is essentially a test which must be very carefully controlled. The pitfalls are numerous and mistakes easy. Unless the serologist adopts a uniform technique errors will creep in. Consequently laboratories where large numbers of tests are carried out, and where the results are carefully checked by the clinician, will tend to furnish more reliable results than isolated laboratories performing small numbers of tests at comparatively long intervals. The M.R.C. recommended that where tests are carried out for official purposes not less than 100 tests per week should be performed, preferably in batches of about 50.

It is most unfortunate that no general standardisation of the W.R. has been found possible, but seeing that so far no one method has been able to oust all the others it seems probable that the method employed in the largest number of cases, adequately checked, will give the most reliable results. Moreover, since the various reagents on the market vary very much in potency and reliability, it follows that a large, well-equipped laboratory which makes its own reagents will have a considerable pull over a small one when they have to be purchased from outside.

Notation.

With the large number of methods employed there are of necessity many notations. Some use + + + +, + + +, + +, +, and − or negative to indicate strongly positive, moderately positive, weakly positive, doubtful, and negative results respectively. Others employ numerals from 0 to 4 to indicate the amount of hæmolysis in the various tubes of the reaction; thus Kolmer uses 4 4 4 4 4 to indicate a strong positive, 4 4 0 0 0 to indicate a moderate positive, and *0 0 0 0 0 to indicate* a negative. The method most commonly employed in this country is that recommended by the Health Section of the League of Nations: this consists of + +, +, ±, − to indicate strongly positive, positive, doubtful, and negative respectively. In any case it is a sound plan for the pathologist in giving a result to amplify the report by stating in brackets after his notation sign the words applicable to the result—e.g., + + (strongly positive); ± (doubtful).

Technique of Taking and Forwarding Specimens.

Varying amounts of blood serum are required for the performance of the W.R. according to the method employed. Generally 1 c.cm. of blood or 0·25 c.cm. of serum is the minimum amount required, but most pathologists will be grateful to the clinician who sends a more than adequate supply; few patients are any the worse for losing 5, 10, or even 20 c.cm. of blood, and an ample supply of serum enables the test to be repeated if necessary, or confirmatory flocculation tests to be carried out.

Much the best method of obtaining the blood is by venepuncture, which in adults is usually simplicity itself, though the blood may be obtained by pricking the finger or lobe of the ear.

Venepuncture.—For venepuncture a sterile all-glass or Record syringe, and a fine sharp hollow needle are advisable. The syringe should be rinsed out with sterile physiological saline before use, especially if it has been sterilised with spirit or by boiling. Spirit may interfere with the reaction, and water present will cause more or less hæmolysis of the blood, and so discolour the serum. A good specimen is more likely to furnish a satisfactory result than a bad one.

The patient should be *seated* or *lying down* with the arm lying on a small table, palm uppermost. A tourniquet, *consisting of a length of* rubber tubing, is fixed round the upper arm and held by the patient, or tied in a half bow so that it can easily be released with one hand by the operator. A prominent vein over the antecubital fossa is chosen, and the skin over it painted with tincture of iodine: in this area the veins are comparatively fixed, and do not tend to slip away from the point of the needle. If the veins do not stand up well the patient should be instructed to hang the arm down and open and clench the fist, finally keeping it closed, or the arm may be immersed in warm water for a few minutes. The tourniquet should be sufficiently tight to make the veins stand up but not so tight as to obstruct the arterial circulation. The needle is attached to a syringe, preferably having the nozzle situated close to the periphery of the distal end (not in the centre, as in the ordinary type of syringe): this arrangement enables the needle to be held more in line with the vein. A point is chosen immediately over or just to one side of the vein; the skin is first punctured, then, when the point of the needle is located under the skin and over the vein, it is pushed on and will enter the vein with a well-marked but indefinable sensation of having overcome a slight resistance. The advantage of doing the puncture in two stages is that there is less likely to be an escape of blood following withdrawal of the needle. Sufficient blood is now withdrawn, the tourniquet released, the needle withdrawn, a pad held firmly over the site of puncture, and the patient instructed to hold his arm *straight* up vertically for a minute or so. No dressing is required unless blood oozes when the arm is allowed to hang down. The blood should be transferred to a sterile test-tube immediately and not allowed to clot in the syringe.

A simpler method is to use a needle to which a short length of rubber tubing is attached; the needle is held between the thumb and first finger, whilst a test-tube into which the rubber tubing leads is grasped by the ring and little fingers. This obviates the use of a syringe—but entails the use of a wide-bore needle, as otherwise the blood may not flow freely. Many forms of apparatus for taking the blood are on the market, but the above method is rapid and simple.

Serum by Post.

In cases where the blood has to be sent through the post, and/or when the test is not likely to be carried out within 24 hours of taking the specimen, it is preferable to send serum only, not whole blood. After the blood has stood in the test-tube for a few hours the serum separates quite readily; if it does not, a platinum wire or glass rod should be used to separate the clot from the sides of the tube, and the tube should be placed in warm water for a short time. When the serum has separated it should be poured out into a small sterile glass tube, and the latter tightly corked. If whole blood is sent through the post, and especially if the weather is warm, hæmolysis is apt to occur; this may vitiate the test or render its performance impossible. The specimen should be kept sterile as far as possible; infection with organisms, if heavy, may render the serum so anticomplementary that the test will fail and the pathologist will be unable to furnish a report. Though it is wise to test a specimen of serum as soon as possible, preferably within a day or two, a satisfactory result can be obtained after several weeks or even months. I have tested sera sent from West Africa, India, and Mesopotamia by ordinary post.

---

[1] Medical Research Committee Special Report Series, No. 14, 1921.

When sending specimens of blood or serum through the post it is necessary to comply with the Post Office Regulations on the subject. The specimen must be (1) sent by letter, *not* parcel, post; (2) enclosed in a receptacle securely closed and placed in a box in which it cannot shift about; (3) surrounded by a sufficient quantity of some absorbent material, such as cotton-wool or sawdust, so as to prevent any possible leakage; (4) marked "fragile, with care, pathological specimen."

It is most desirable that all sera should be accompanied by clinical details giving a short account of (*a*) situation and character of the lesion; (*b*) length of time the disease has existed; (*c*) treatment administered (if any), both local and general; (*d*) results of previous tests with dates; (*e*) any special remarks. This information enables the pathologist to give a much more satisfactory opinion as to the interpretation of the reaction—an opinion which should always be expressly asked for.

T. E. OSMOND, M.B. Camb.,
Pathologist, Venereal Diseases Dept., St. Thomas's Hospital, London.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Comdr. (D.) H. M. Meek is placed on the Retd. List at his own request.

Surg. Lt.-Comdr. (D.) J. F. Place to be Surg. Comdr. (D.).

Surg. Lts. E. C. Davis, A. L. McDonnell, and S. G. Weldon to be Surg. Lt.-Comdrs.

The following appointments are notified: Surg. Comdrs. C. E. Greeson to *President*, and E. St. G. S. Goodwin to *Victory*.

ROYAL NAVAL VOLUNTEER RESERVE.

The following appointments are notified: Surg. Lt. A. R. Thomas to *Victory*, for R.N. Hospital, Haslar, for training, and Proby. Surg. Sub-Lt. R. H. Wheeler to *Pembroke*, for R.N. Barracks, Chatham, for training.

ROYAL ARMY MEDICAL CORPS.

Capt. R. R. Evans to be Maj. (Prov.).

Lt. (on prob.) P. D. Johnson resigns his commn.

ARMY RESERVE OF OFFICERS.

Lt.-Col. H. V. Bagshawe, having attained the age limit of liability to recall, ceases to belong to the Res. of Off.

SUPPLEMENTARY RESERVE OF OFFICERS.

Lt. A. Hemingway to be Capt.

TERRITORIAL ARMY.

J. H. B. Livingston (late Offr. Cadet, Glasgow Univ. Contgt., Sen. Div., O.T.C.) to be Lt.

DEATHS IN THE SERVICES.

Surgeon Captain Richard Miller, R.N., retd., who died after an operation on Sept. 12th at the age of 67, was a graduate of Trinity College, Dublin, and entered the Royal Navy as surgeon in 1887. Two years later he received the Bronze Medal of the Royal Humane Society for jumping overboard from the *Iron Duke* off Malta, and going to the assistance of a corporal of marines. In 1903 he was promoted to fleet surgeon, and, after service in battleships, was placed in charge of the Royal Hospital at Yarmouth. In 1916 he became medical officer of the battle cruiser *Princess Royal*, and a year later retired on age limit with the rank of surgeon captain.

Special Articles.

BACILLARY DYSENTERY IN AN INDUSTRIAL AREA.

BY J. A. CHARLES, M.B. DURH., M.R.C.P. LOND., D.P.H.,
DEPUTY MEDICAL OFFICER OF HEALTH, NEWCASTLE-UPON-TYNE;
AND
S. H. WARREN, M.R.C.S. ENG., D.P.H.,
DIRECTOR, PUBLIC HEALTH LABORATORY, UNIVERSITY OF DURHAM COLLEGE OF MEDICINE.

THE English text-book descriptions of bacillary dysentery almost always present to us a disease of great antiquity, the concomitant and curse of our multitudinous military operations from Agincourt to Gallipoli, an endemic disorder which nowadays limits its activities, for the most part, to the tropical and subtropical zones. They suggest that its presence in these islands is infrequent, showing itself occasionally in sporadic cases, in outbreaks affecting mental institutions and their inmates, or in larger epidemic manifestations, such as the Glamorgan outbreak of 1921 where infected water or milk is the chosen medium of dispersal. Even the causal organisms are indifferently differentiated, and while due regard is paid to the toxicity of the bacillus of Shiga, those other members of the group which are associated with the names of Flexner and Sonne are regarded as being relatively avirulent and often almost non-pathogenic. These facts are insufficiently understood, despite the work of Nabarro,[1] and the Aberdeen[2] and Glasgow[3] investigators.

It is our intention in this article to combat certain of these conceptions, and to endeavour to demonstrate that in some parts of Great Britain bacillary dysentery is not a rare and spectacular occurrence, but a fact of everyday life.

History of the Investigation.

Proven cases of bacillary dysentery have been discovered from time to time during the last eight years in Newcastle and the two northern counties of Northumberland and Durham, and records of the isolation of the causal organisms are in existence in the Public Health Department of the University of Durham College of Medicine Bacteriological Laboratory. The present detailed inquiry dates from March, 1928, when three members of a Newcastle household fell ill with symptoms which suggested a food poisoning infection. Bacteriological investigation showed that these mild cases were due to the *Bacillus dysenteriæ* Flexner, Type Z. Within a month two sudden deaths occurred in boys aged 8 and 9 years respectively, and post-mortem and bacteriological examination proved that the cause of death in each case had been a dysenteric infection by a Flexner organism.

In consequence of these facts the medical practitioners of the city were circularised and requested to notify to the medical officer of health any cases where signs and symptoms suggestive of dysentery were present, with a view to their thorough investigation and hospitalisation if necessary. Up to June 30th of the present year this request had resulted in the notification of some 355 cases of suspected dysentery. Many of these were discarded on clinical or bacteriological grounds, but from this source and through other channels of inquiry—e.g., inquests, &c.—information was obtained of 141 cases of true bacteriologically proven bacillary dysentery.

The 111 positive and 80 suspected cases which were admitted to the City Hospital for Infectious Diseases, during the period under review (March, 1928, to June 30th, 1929), afforded ample material for clinical and bacteriological investigation, the results of which are synopsised in the following sections.

Clinical Features.

Primarily a distinction must be made between the ordinary simple case, which though of varying severity yet progresses steadily to convalescence and cure, and the acutely toxic one, in which onset, the development of symptoms, and death follow one another so swiftly that the whole course of the disease requires but 24 hours for its completion. The ten fatal cases in this series were all examples of this fulminant entero-colic dysentery.

In the mild cases the onset is usually gradual. A simple malaise and headache develop, and are occasionally associated with vomiting. There is fever, and the temperature reaches 100° or 101° F. Abdominal pains of colicky type follow, and in the course of a few hours these are succeeded by the passage of a few loose motions. After the bowel has been emptied of its fæcal contents, the stools rapidly increase in number and mucus and blood make their appearance. The presence of these in the stool may take one of several forms, occurring either as the true red-currant jelly stool of dysentery, or a watery mucous motion in which float shreds of blood-clot, or the grumous stool flecked with mucus and blood. All these have been observed, and the presence of dysentery bacilli in them confirmed. The diarrhœa in certain cases is almost continuous, and 20–30 stools in the 24 hours are not infrequent. Throughout this stage the colicky pains are invariably present, and relief follows the evacuation of the bowel. Tenesmus, particularly in adults, is a common symptom, while pain on deep pressure over the abdomen, except in the region of the pelvic colon, is comparatively rare. Enlargement of the spleen has been observed in not more than 10 per cent. of cases. Furring of the tongue is generally present. The appearance of the patient varies according to the severity of the attack, but is usually one of distress and discomfort. The commencement of treatment results, almost immediately, in the disappearance of the blood and mucus from the stool; the pyrexia gradually diminishes until coincident with the improvement in the intestinal condition, it ceases about the eighth day of the disease along with the diarrhœa. Complications have been very few. Nephritis and broncho-pneumonia were each found as a sequela on one occasion, though albuminuria during the early stage of fever was relatively common. In one extra-mural case, which was reported to us, there was a definite polyarticular arthritis. The bronchitic signs which the Aberdeen observers associated with infection by the Sonne bacillus were never met with. Personally, we found nothing to differentiate between the cases caused by the several types of dysentery organisms, except that Sonne infections appeared on the whole to be milder, less frequently associated with the cardinal signs of pyrexia, tenesmus, and blood and mucus, and more liable to present the features of a mild diarrhœa with semi-solid rather than liquid stools.

Only one patient suffered a relapse—and this was while she was still in hospital. Further, although multiple, more or less simultaneous cases from individual houses have been frequently encountered, there has been no evidence of "return" cases. Bacteriological examination of a certain number of patients after discharge from hospital has given negative results.

A few figures may be of interest. The average duration of pyrexia in all cases was seven days, with 2 and 16 days as the extremes of duration; blood and mucus in the stool were generally present for four days with recorded limits of 1 and 16 days; diarrhœa continued on an average for about a week, but was found in several cases for only two days and in one for 19 at least. Some idea, although admittedly only an approximate one, of the length of time during which the causal organism could be found in the stools, can be gathered from the fact that the average period from the outset of the attack to the ascertainment of the first negative stool was 10 days. On this basis the shortest period of infectivity was 0, and the longest—which practically amounted to a carrier state—71 days.

Fatal Cases.

In fatal cases the onset is extremely sudden, and the symptoms are toxic rather than diarrhœic. Headache and vomiting are invariably present, the temperature at first may be as high as 102° or 103°, but even though the typical colicky pain, diarrhœa and blood and mucus may make their appearance, they are of little moment in the presence of the profound toxæmia, coma, collapse, and circulatory failure which develop so rapidly in these cases. A common history is that of a child well enough to attend school in the morning, who after dining at home, and feeling perhaps not quite so well thereafter, returns to school for the afternoon. After school he is sick, lies down, refuses his tea, and then appears to sleep. Later in the evening the prolonged drowsiness or a change in his colour attracts the parent's attention. A doctor is summoned, the patient removed to hospital, but even the most energetic treatment with stimulant and serum fails to rouse him, and death occurs within 18 to 24 hours of the onset.

Diagnosis.—Both in the mild and the fatal cases diagnosis has certain pitfalls. The commonest errors are to regard the condition in children as a non-infective enteritis, and in adults to suspect the presence of a true food poisoning infection. But other diagnoses such as intussusception, encephalitis lethargica, enteric fever have been made, and on two occasions a moribund and stertorous child has been admitted to hospital as suffering from laryngeal diphtheria. One particularly interesting case which was brought to our notice by Dr. J. W. Lickley, of the Fleming Memorial Hospital, was that of a child with a facial paralysis, due to a toxic neuritis, which had appeared as a sequel of a proved infection with Flexner dysentery.

Treatment.—The routine treatment of all simple cases has comprised rest in bed, light diet, colon lavage, and the administration of sodium sulphate in appropriate doses. Serum treatment with a polyvalent Shiga-Flexner serum has been employed comparatively freely. Its place in the therapeutics of our cases may be summed up quite shortly. Generally the mild cases as they occur in children do not require serum; the severer ones in adults yield quickly to its administration, and in the relief of symptoms, particularly of the tenesmus, it is remarkably effective; in the fulminant cases serum, however administered, has never succeeded in combating the toxæmia.

Post-mortem Appearances.

It will be remembered that all the deaths in the present series occurred in cases of the fulminant type of the disease, and the findings of the ten post-mortem examinations performed differed but slightly from one another. No case showed the signs of chronic dysentery, nor yet of the ordinary acute type of the disease. In every instance the pathological findings indicated an inflammatory condition of both ileum and colon—the entero-colic type of the disease—and in the majority the enteritis predominated. The changes were most marked in the lower third of the ileum, though in one case it was the upper part of the jejunum which appeared to be chiefly affected. The blood-vessels in the wall of the gut were generally engorged, and on opening the peritoneal cavity it was easy to locate the portions of bowel involved by their congested appearance. Of actual peritonitis there was never any trace. The appearance of the bowel wall internally was invariably that of a folliculitis, passing on to follicular ulceration, but the Peyer's patches, though prominent and hyperæmic, were rarely ulcerated. The condition of the colon was similar to that of the small intestine, though to a less degree. Neither large nor small bowel was ever found to be the seat of chronic thickening, though recent œdema was constantly present. In several cases the mesenteric glands were found acutely enlarged, and in one case there was a slight degree of splenomegaly. Toxic changes were invariably present in the heart, kidneys, and liver.

Of the ten post-mortems, only one was negative bacteriologically, but from this case shortly before death a stool was obtained from which a Flexner organism was isolated. All the others were positive, and the causal dysenteric organism was isolated from one or more sources. The results of the bacteriological examinations of the specified organs are shown in Table I.

TABLE I.

Organ.	P.M. specimens examined.	Positive for dysentery organism.
Stomach	5	0
Small intestine ..	10	5
Colon	8	6
Spleen	7	1
Liver	2	1

It is interesting to note that though gross pathological changes were more frequently observed in the small intestine, a higher proportion of positive cultures was obtained from the colon.

Epidemiological Features.

In an interim report on 22 of the present cases which has been published by one of us,[4] a comprehensive review was made of a number of possible epidemiological agents in the causation of the disease, and the relation of water, milk, milk products, ice-cream, prepared meats, shell-fish, watercress, salads, flies, epizoötics, school attendance, and sanitary conditions was carefully investigated. In view of the fact that the results of this critical review were entirely negative—a conclusion which has been borne out by continued investigation on more recent cases—it is not proposed to discuss these individual features further. Some consideration of certain other factors is, however, necessary.

Age and Sex Distribution.—Table II. gives the age distribution of the 355 suspected cases, and the age, sex, and mortality distribution of the 141 proved cases.

TABLE II.

Suspected Cases of Dysentery.

Total 5(1)	28(1)	46(1)	38(7)	4	15	5	—	141(10)

M. = Male; F. = Female. (The figures in parentheses which are included in numbers by which they stand indicate fatal cases.)

Several facts are at once apparent—viz., the comparative rarity of the infection under the age of 12 months, the heavy incidence on children between 2–5, the lower death-rate in females, and the very high mortality amongst boys from 5–15. Further, it is evident that adults are by no means immune from infection. *It is probable that the encouragement* which has been given to breast-feeding of infants in Newcastle accounts for their freedom from the disease, for of the five in the first age-group who contracted the disease only one was breast-fed. Above the age of 1 the same adherence to the principles of sound dietetics is lacking. There is a tendency to simplify the domestic arrangements by giving the toddler "the same as we," which results in his regarding any stray article of food, however broken or dirty, as suitable material for ingestion. The freedom of girls from the presumably massive infections which are responsible for the toxic dysenteries so common in boys may be due to the more delicate habits of the female, or to a statistical illusion which a larger number of cases will remove.

Seasonal Incidence.—As will be seen from Table III., cases of bacillary dysentery have occurred throughout the year, though an increased incidence is apparent in the warmer months—e.g., August, September, 1928, to April, May, and June, 1929. Our figures, however, are not free from the error that as the knowledge of the condition extends amongst medical practitioners so also do the number of positive cases increase. Accordingly, it is impossible to make any strict comparison for example between the incidence of dysentery upon children under the age of two and the deaths registered under "enteritis" in the same age-group, and so obtain figures which might show the presence or absence of any connexion between the two.

Distribution of the Cases.—The 141 positive cases occurred not only singly, but also as multiple cases in individual households.

There was one hospital outbreak made up of seven cases, four domiciliary groups of three each, 13 where two patients were affected, and 96 single cases. Among the latter, however, there were 16 which gave histories of associated cases of diarrhœa in the same dwelling, usually before the discovery of the positive case. These cases were often highly suggestive of dysentery, but were either not available for examination early enough or were bacteriologically negative.

Mention may be made here of certain facts which will be considerably amplified later. No fewer than six types and varieties of dysentery organisms have been found active in the causation of the disease in Newcastle. This alone is highly suggestive of the endemicity of the disease, provided always that it can be shown the types do not change one into the other. The first point of evidence to suggest that the types do remain constant and stable is the persisting specificity of the domiciliary infection. By this we mean that whenever multiple cases have occurred in a dwelling the same type of organism has been isolated from every case in that house.

Out of 17 such domiciliary outbreaks, there was only one in which this principle did not hold; and in this instance a newly arrived lodger who had been roughing it in hedges and lodging-houses developed a Flexner W infection in the same house in which a child had previously had a Flexner Z dysentery. The circumstances of the lodger, and the negative results of further investigation of the child, led us to regard this as a coincidental rather than as a transmitted infection.

The usual sequence of the disease in a household is interesting. Simultaneous onset in several of the members is rare. Most commonly the illness of one child is followed a little later by the classical signs in another, and lastly the mother, who has been doing the nursing, falls sick herself. The hospital outbreak of seven cases already referred to occurred in a female diphtheria ward, and was apparently due to the admission of an undetected Sonne carrier. Here, again, there was no simultaneity of attack, but only the customary case-to-case infection, which was followed by the isolation of a Sonne bacillus in every instance. The disease was widespread throughout the city, and 17 of the 19 wards yielded cases, while the unaffected districts were high-class residential suburbs.

One ward—in large part owing to the keenness of its medical practitioners—supplied 51 cases spread over the 16 months' investigation. Twenty of these occurred in a large housing estate of 24 blocks of flats which had been built during the war. This property, by name *Rochester* Dwellings, with its 384 dwellings and 1800 inhabitants, was the subject of intensive research. Three distinct organisms were associated with the 20 cases occurring there, and the principle of the persisting specificity of domiciliary infection *not only applied, but in several instances over a period of* months, has shown itself true for whole blocks of flats.

Lastly, a word may be said as to the occurrence of bacillary dysentery in the surrounding neighbourhood. Ten of the 141 cases notified were extra-mural cases, which had been admitted from towns and villages in Northumberland and Durham. In only one of these cases could infection be traced to Newcastle. During the same period the laboratory records show that 14 more cases were bacteriologically diagnosed from seven different sources in the two counties. Evidence of sporadic outbreaks, both in the city and the neighbouring counties, has gradually accumulated. From the beginning of 1922 to the commencement of the present investigation, there are records of 12 outbreaks, reports on three of which have been published by Breakey and Clayton,[5] Clayton,[6] and Warren.[7] The organisms implicated were *B. dysenteriæ* Flexner (various types) on six occasions, a definite Sonne bacillus (1926), and two almost certainly identical organisms which were isolated earlier (1922 and 1923), and regarded as inagglutinable Flexners, the original strain of the Newcastle bacillus, an indefinite *B. dysenteriæ* Schmitz, and an atypical Shiga organism.

Overcrowding.—There is no need to stress the importance of overcrowding, with its manifold opportunities for personal contact, in the spread of infectious disease. The census definition which lays down that overcrowding is present when the number of persons per room in a dwelling exceeds two is the simplest for our purpose, and in 1921, on this basis, 33·6 per cent. of the population of Newcastle were living under such conditions. Since that date 6000 new houses have been built and the general overcrowding has diminished, but in the case of the population from which the dysentery cases came, it was even worse than the average for 1921, for 52·6 per cent. of them came under the census definition. Further, of the eight Newcastle families amongst which fatal cases occurred, 94·6 per cent. of their members were overcrowded. Actually the average number of persons per room in those households was four.

Hospitalisation of cases of acute dysentery is of obvious practical value in many ways, and not least because it removes a focus of infection from a house, and incidentally reduces the overcrowding. The following facts are put forward as being highly suggestive. In the first eight months of the present investigation there were 58 cases with eight deaths, occurring in 46 outbreaks, of which 10 or 22 per cent. were multiple. The corresponding figures for the last eight months were 88 cases with two deaths, occurring in 69 outbreaks, eight of which were multiple—a percentage of 12. Apart from these figures our feeling is that with the spread of an increased clinical consciousness of the disease among practitioners, and the better appreciation of the hospital facilities available, the multiple case-rate, and the case-mortality have steadily diminished.

Mode of Infection—Our conception of the spread of the infection is that it occurs through close and intimate contact of infecting persons with others or with their food, its preparation and service. The conditions under which many of our patients lived were such as made ordinary cleanliness very difficult, and the proper hygiene of the kitchen and food storage almost impossible. The actual sanitary conveniences of these families were good—apart from the fact that they were shared too frequently in common with others. Without doubt, the missed case of dysentery is the principal factor in the diffusion of infection. On several occasions we have obtained a history of an earlier case in a house, and confirmed it by agglutination tests, which invariably showed the same causal organism both in it and the later case or cases.

We have not found definite and conclusive evidence of the existence of carriers. In three instances, however, we have come across suggestions of their presence.

1. A case of enteric during the convalescent period yielded a stool containing Sonne bacillus, without history of recent attack or exposure to infection.

2. The seven cases of Sonne dysentery in a female diphtheria ward occurred consecutively amongst convalescent patients, in whom again both recent attacks and exposure to infection could be ruled out.

3. One patient with Flexner "Z" dysentery (and probably a double infection with Sonne also) did not give a negative stool until 71 days from the onset. For the last eight weeks of this period he was entirely free from symptoms of any description.

Bacteriological Data.—From 471 specimens submitted to examination, dysentery bacilli were isolated on 210 occasions. It is necessary to observe that the number of examinations carried out was the absolute minimum necessary for purposes of diagnosis, and for determining whether a patient awaiting discharge from hospital was free from infection. If a single stool examination did not confirm the clinical diagnosis no further examination was made. This voluntary restriction of the field of inquiry undoubtedly prevented a larger proportion of positive results being obtained from the 355 cases notified.

After a clinical cure had been established, one negative stool was regarded as sufficient to enable a patient to be discharged from hospital. This policy seems to have been justified by results. Only one relapse occurred, and even though discharged cases are still kept under observation, and attempts made to associate them with new notifications, no evidence of any return case is available as yet.

Specimens from cases of chronic bacillary dysentery were not met with. Generally speaking the stools obtained from acute cases of the disease consisted of watery muco-pus, and more frequently of muco-pus, sometimes with blood and often bile-stained. The convalescent stool was usually composed of fæcal material. The negative results of microscopical examination for amœbæ, intestinal parasites and cysts, led to the discarding of this form of examination at an early date.

The actual diagnosis of bacillary dysentery was made by the isolation of a recognised dysentery organism from the fæces. Tests for agglutination in human sera were not found to give marked and clear-cut results, and their use was limited to confirming whether a cured clinical but non-bacteriologically proven case with a suggestive history had really been suffering from dysentery, and to ascertaining whether such a case occurring early in a domiciliary outbreak had been infected with the same type of organism as was isolated later from other members of the family.

The routine method of examination consisted in washing pieces of muco-pus in normal saline, and then sowing two or three bile-salt lactose-peptone-neutral-red agar plates. All specimens, where food-poisoning was suspected, particularly from post-mortem cases, were also inoculated into brilliant-green peptone water, and subsequently plated as above after 24 hours' incubation at 37° C. This procedure of brilliant-green enrichment practically never resulted in the isolation of dysentery bacilli. On direct plates, however, the results varied from an almost pure culture of a dysentery bacillus to the presence of one single colony amid many coliform ones.

The dysentery organisms isolated belonged to the three main groups: (1) *B. dysenteriæ* Flexner; (2) *B. dysenteriæ* Sonne (III); and (3) the Newcastle bacillus. The various types were identified both by their biochemical reactions and serologically. Occasionally when there was some doubt, motility was tested, but this was not done as a routine, and in no instance was any of the three groups found to be motile.

Biochemical Reactions.—For this purpose the following peptone water sugars were used—glucose, lactose, saccharose, mannite, and dulcite. Litmus milk and peptone water for indol production were also employed.

The reactions of the three groups were as follows:—

(1) The Flexner group uniformly gave the recognised sugar reactions—acid with glucose and mannite, and no change in lactose, saccharose, or dulcite. In litmus milk slight acidity followed by alkalinity was the usual change, only varied by the milk occasionally not going definitely alkaline. Indol was produced by most of the strains, but just a few were definitely negative. All reactions were incubated for at least ten days.

(2) *B. dysenteriæ* Sonne III. All the strains which we have identified as belonging to this group have given uniform results in that they rapidly produced acid in glucose and mannite, and after incubation at 37° C. for at least 14 days, showed late fermentation of lactose and saccharose, acid production in milk, and non-production of indol. These findings confirmed the description of Kerrin,[8] except that maltose, dextrin, and xylose were not used. None of the strains appeared to belong to the *dispar* group of Andrewes.

(3) The isolation of the Newcastle bacillus as described by Clayton and Warren[7] has formed part of this investigation. Its biochemical reactions conformed to those given by these authors, and are as follows: Acid is produced in

glucose, and acid with possibly a little gas in dulcite after four or five days. Mannite, lactose, and saccharose give no change. (When lemco broth sugar media were employed, acid and gas were produced in glucose in 24 hours, and in dulcite in four to six days). Litmus milk remained unaltered, and no indol was produced.

Serological Investigations on all isolated organisms were also carried out, and no identification was made until this had been completed. In this work we received great assistance from Dr. W. M. Scott, of the Ministry of Health, who examined and confirmed the identification of the majority of our strains.

As regards the *Flexner group*, the serological races of these organisms as established by Andrewes and Inman[10] formed the basis of the typing of the strains isolated by us. The isolated organism was first subjected to a polyvalent Flexner serum, and if agglutinated, was then put up to the five type sera—V, W, X, Y, and Z. In our case simple agglutination with impure type sera was employed, and saturation tests were not used. Scott used chiefly pure specific type sera from which the group agglutinins had been removed. Such tests enabled us to confirm the biochemical reactions which placed these organisms in the Flexner group, and to separate them out into the various serological races, V, W, X, Y, and Z.

By simple agglutination we found a few W and X strains, which appeared to be more closely related to the Y group than is normal, but when subjected by Scott to specific type sera, these organisms all proved to be simple W or X strains.

In all, 109 Flexner strains were isolated and were distributed as follows: V, absent; W, 51; X, 8; Y, 1; and Z, 49. The only variation found in the Flexner group was that occasionally one met with an organism which agglutinated rather poorly, but even such a one could be typed. Further, a mixture of more than one type of Flexner organisms was never encountered in any specimen examined. This search for a multiplicity of Flexner types in one stool was not made as a routine, but from time to time all the colonies taken off a plate (4 or 5, as a rule, when possible) were put up for typing and were found to be identical. This was done with W, X, and Z strains.

The serological features of the *Sonne group* can be summarised as giving definite agglutination with Sonne III serum, and a negative reaction with polyvalent Flexner serum. At first we encountered the usual difficulty in getting recent strains of Sonne to agglutinate, but no difficulty was experienced later, when the significance of agglutination of the rough and smooth stages of the organism had been appreciated. A mixed rough and smooth serum obtained from Scott was of great use in quickly identifying this group, and a smooth serum prepared in the laboratory has been found so far to agglutinate all recently isolated cultures quite well.

The serological characteristics of the *Newcastle bacillus* have been described in detail in their second paper by Clayton and Warren.[11] In short, it may be said that although this organism is serologically distinct, it bears some relation to the Flexner group.

It is noteworthy that all the types isolated with the exception of Y were possessed of lethal powers to a greater or lesser degree. Their association with the ten fatal cases was as follows: Flexner W, 3 cases; X, 1; Y, 0; Z, 2; Sonne, 2; Newcastle bacillus, 2.

The seasonal incidence and distribution between the sexes of the various organisms are also recorded in Table III.

TABLE III.

Type of organism.	1928										1929						Males.	Females.	Totals.

The figures in parentheses, which are included in the numbers alongside which they stand, indicate fatal cases.

Discussion.

We have still to speak of certain observations on the variability of the dysentery bacilli isolated from the 141 cases in the series. Two facts have already been mentioned. First, that where multiple domiciliary cases occurred, the group and type of the organism were the same for each individual case in the series; secondly, that when several colonies of dysentery bacilli were taken from a plate sown from the fæces of a single case, these colonies when typed were all found to consist of one and the same strain of organism.

Attention is now directed to another series of observations. In 128 out of the 141 proven cases, the examination of the stools was repeated until a negative result was obtained. We found that—

96 patients gave 1 pos. stool followed by 1 neg. stool.
17 „ „ 2 „ „ „ 1 „ „
8 „ „ 3 „ „ „ 1 „ „
2 „ „ 4 „ „ „ 1 „ „
1 „ „ 5 „ „ 1 „ „

The type of organism remaining unchanged throughout the respective serial examinations.

Four patients gave variations in the types of organism isolated as follows:—

Patient.
Z 734 gave Flexner W, then Fl. Z, then neg. stool.
Z 341 gave Fl. Z twice, then Fl. W, once, then neg. stool.
Z 294 gave Fl. W twice, then Fl. X once, then neg. stool.
Z 251 gave Fl. Z four, then Sonne III once, then Fl. Z three, then neg. stool, which was repeated two months later.

There are thus 28 serial investigations where the same organism occurred two or more times, and four where there were variations. With regard to one of these four cases, we consider that the occurrence of Sonne III. in the middle of the course of the obvious Flexner Z case (No. Z 251) was indicative of mixed infection. As for the others we are not prepared to state whether they are examples of mixed infection, or of mutation, or even, possibly, of errors in technique. Our opinion is that these various Flexner types do not change one into the other, but maintain their identity in the same way as do the Sonne and Newcastle organisms.

Conclusions.

(1) Bacillary dysentery is a relatively common disease. Our experience, together with those of Nabarro and the Glasgow and Aberdeen observers, suggests that in certain areas it is undoubtedly endemic. (2) Mild, severe, and fatal cases are all to be met with, and conform in the main to the classical types of the disease. (3) Its seasonal incidence is not limited to the warmer months of the year, and for this reason and because of its low attack-, and still lower mortality-rates among children below the age of two years, it does not appear to have any definite association with the infective summer diarrhœa of infants. The causation of this latter condition requires further and extensive research. (4) Six different organisms belonging to the Flexner, Sonne, and Newcastle group of dysentery bacilli have been found in association with the disease. It is not improbable that in other

areas the prevailing types may be different. (5) In view of the persistence of the same type of organism, (*a*) in multiple domiciliary cases, (*b*) in the examination of several colonies from a single plate, and (*c*) in the large majority of serial examinations from the same case, our opinion is that these various causal organisms breed true.

We beg to offer our thanks to Prof. Harold Kerr, medical officer of health, Newcastle-upon-Tyne, for the facilities for conducting this investigation which were so freely placed at our disposal, and to Dr. W. M. Scott, of the Ministry of Health, for advice and assistance in many ways too numerous to mention. This paper, moreover, would be incomplete without an acknowledgment of our indebtedness to Dr. F. H. A. Clayton, *in conjunction with whom the inquiry was* initiated.

THE STATE OF THE PUBLIC HEALTH.

(Concluded from p. 474.)

WE have already dealt with the general lessons of the Annual Report[1] of the Chief Medical Officer of the Ministry of Health for 1928 (August 31st, p. 460), and with the sections devoted to maternal and infant welfare, and the insurance medical service. The following is a brief summary of the remaining sections of the report.

The Local Government Act.

The Report discusses the evolution of the poor-law and the development of public health administration in England since the Reform Act of 1832. It urges medical officers of health to be prepared to advise their councils on such general questions as:—

1. The desirability of discharging certain of the transferred functions through some committee other than the Public Assistance Committee, to which most of the transferred powers otherwise stand referred or may be delegated.

2. The advisability and practicability of providing certain forms of medical assistance under the Public Health and other Acts rather than under the Public Assistance Committee and the Poor-law Act.

3. Whether in districts where it is impracticable to declare that all assistance for the sick should be provided under the Public Health Acts, it may be desirable to appropriate one of the transferred institutions to hospital purposes and to administer it under one or other of these Acts.

4. The desirability in counties which have decided to provide certain forms of relief under the Education Act, 1921, or the Maternity and Child Welfare Act, 1918, of delegating the provision of such assistance to other local authorities.

The principal question is how many and which of the poor-law medical services can be absorbed into the public health organisation of the area, and how many must remain *ad hoc*. Each individual area must aim, not at providing every service everywhere, but at supplying as effective and complete a service as is practicable. The Report advises local authorities and their medical officers to consider the medical functions of boards of guardians on the one hand and those of county and county borough councils on the other hand, and to devise an organisation most likely to prove effective for the joint performance of these functions in the varying circumstances. It offers a most valuable guide in a complete review of the medical functions of both bodies, and mentions the principal matters which will require the prompt attention of medical officers of health. Perhaps the most essential thing to secure is effective coördination, not only between the various branches of the service and the various institutions carrying out related duties, but also between local authorities and voluntary agencies and between institutional medical treatment and environmental hygiene and sanitation. The services which must now be woven into a unified organisation on behalf of the whole community include water-supply, drainage, refuse collection, housing, smoke abatement; the control of the food- and milk-supply; health in the office and factory; maternity, infant and child welfare; school medical service; isolation hospitals and treatment of fevers; baths and wash-houses; cleansing of persons, and the direct treatment of such diseases as tuberculosis and venereal and mental disorders. "For the first time in the history of the public health service the medical officer of health has a direct and ample opportunity for closely and effectually coördinating in his area all the varied medical services of the State."

Epidemics during 1928.

The outstanding events of the year in general epidemiology were the continued prevalence of small-pox (to which we referred in an earlier issue[2]), an unusually large incidence of scarlet fever, and a widespread epidemic of influenza in the winter of 1928–29. The diphtheria figures are also greater than during the preceding quinquennium, and the mortality was 5·2 per cent. Seventeen borough councils in London, but only 19 local authorities in other parts, are now providing immunisation against diphtheria. The personal influence of the health visitor, supported by a simple pamphlet, usually provides a steady flow of applicants at the clinic. Toxoid-antitoxin mixture is generally used, but a preparation of toxoid alone is equally safe and is said to be equally effective. The experience of the year has strengthened belief in the value of the method, but has shown that better results are obtained if an interval of two or three weeks is allowed between each injection.

Scarlet fever continues to be mild, with a case mortality of 0·56 per cent. More use is being made of antitoxin, which reduces the tendency to complications, but the progress of active immunisation with toxin is limited by the number of doses required.

Measles ranks second only to whooping-cough as the most fatal infectious disease of childhood. During 1928 it accounted for 4302 deaths. The serum of convalescent patients has been found a very useful prophylactic, although not of much use in treatment.

The deaths from whooping-cough show a decline from 3681 in 1927 to 2970 in 1928.

A study of the outbreaks of enteric and the paratyphoid fevers show that gross sanitary defects are becoming less and less responsible, while special danger lurks in the modern methods of wholesale distribution of foodstuffs, which make it difficult to track down the originator and distributing agents. During July and August nearly 400 persons in London were attacked by paratyphoid B; it was found impossible to trace the infection beyond a wholesale cream dealer who received cream from three different sources, two of them outside the country.

There was a decrease in prevalence of infectious diseases of the nervous system, especially of acute poliomyelitis and, to a lesser extent of encephalitis lethargica. The encephalitis unit at Winchmore Hill is to be extended, and progress has been made with the arrangements for dealing at the Rampton State Institution with cases certified under the Mental Deficiency Acts.

[2] THE LANCET, August 31st, p. 480.

There was no plague in 1928, although plague-infected rats were found on board several ships which reached this country, and the anticipated drift of cholera westward did not materialise. There were three cases of typhus, two of them in Stepney being confirmed by the Weil-Felix reaction. The 683 cases of dysentery notified during the year represents a considerable increase; 58 per cent. of the cases occurred in mental hospitals.

Influenza.

Since the third pandemic wave in March, 1919, there have been several trailers: in January, 1920; in April and May, 1923; and early in 1924. In January, 1925, the whole country was affected. There was only a slight recrudescence in 1926, but in 1927 there was an epidemic of the second order of importance. The year 1928 passed without any influenza, but the news from America caused disquieting anticipations which were fulfilled by a serious epidemic from January to March, 1929. The death-rate per 1000 rose from 0·16 for the great towns in the first week of December to 5·78 in the last week of February. There seem to have been two main waves, the first proceeding southward from Glasgow while the other extended northwards from greater London. None of the signs recognised by epidemiologists as precursors of an influenza epidemic was noticed in this country in the autumn of 1928, and it seems probable that the infection was introduced directly from America and fostered by the exceptionally cold weather in January and February. The public schools suffered considerably in this epidemic, but the disease was mild. Otitis media, however, was a rather common complication. The report discusses the symptoms of influenza and the variations shown in the different epidemics. That of 1928 was characterised by a four days' fever with some pulmonary catarrh and two kinds of onset: sudden, with acute hyperpyrexia, followed generally by rapid convalescence, or insidious, with early subnormal temperature, headache, and malaise, followed by a protracted convalescence. The respiratory system was frequently involved and acute sinusitis was common. The symptomatology, however, varied in different parts of the country. The Report draws attention to the possibility that a rash may be associated with influenza, and outlines the principles of treatment and prevention.

Tuberculosis.

During 1928 a total of 77,881 new cases of tuberculosis were notified, and it is generally agreed that notification is steadily becoming more effective. Nevertheless, 4252 of these new cases were only notified after death, so that there is still room for improvement. The number of deaths from all forms of tuberculosis was 36,623, a decrease on the previous year. Since 1911 the gross death-rate from pulmonary tuberculosis in men has fallen from 1233 to 879 per million, while the reduction in non-pulmonary tuberculosis is from 436 to 188. These encouraging figures show that the measures taken to combat the disease are well worth continuing. The Report discusses the present accommodation for tuberculous patients, the possible modifications under the new Act, and the notification returns. The new Act should greatly assist local authorities in the important task of formulating wise schemes for after-care and technical education. Investigations have been and are still being made into immunisation of the newly-born by Prof. Calmette's method. The results of the special inquiry into tuberculosis among printers have now been published; the report does not explain the high incidence of this disease among printers, but brings out certain differences between the occupational groups which will pave the way for further inquiry.

Cancer and Radium Treatment.

Cancer continues to exact its heavy toll, the death-rate in 1928 per million population being 1425, an increase of 50 on the previous year. Sir George Newman discusses the problems which are brought out by the statistics relating to cancer incidence and reviews the special inquiries which have been made by the Departmental Committee. Especial attention is given to the possibilities of treatment by radium and the effects and modes of application of radiotherapy. The conclusion reached is that radium alone, properly applied, will bring about the disappearance of a primary cancer, in a fair proportion of cases, from the skin, the cervix uteri, and the mouth and tongue. There is not as yet sufficient experience available to claim an equal success against cancer in other parts of the body, and secondary cancer in glands requires supplementary X ray treatment in every case. The Report reviews the organisation of radium therapy in the various European countries and lays down certain guiding principles for its development in England. These are:

1. If this rare element is to be used as economically as possible it should be kept constantly in action, so that as many patients as possible receive treatment.
2. The radium must be maintained in different quantities in containers of various sizes and shapes for use in different regions.
3. The supply of patients at suitable centres must be adequate to keep the radium in continuous use; sending radium to patients causes loss of radio-active time and is likely to lead to inefficient treatment.
4. The services of regional surgical and radiological specialists must be available.
5. Attendants must be fully trained in the use of radium, both from the point of view of skilled service and from that of their own safety.
6. Radium can be used safely and wisely only by thoroughly competent experts.
7. The radiotherapist and the surgeon must coöperate from the very beginning of treatment.

The conclusion is the same as that of the Radiological Subcommission of the League of Nations[2] that radium therapy can only be adequately developed by means of specialised centres serving large populations, and that research and treatment must proceed hand in hand.

Venereal Disease.

At the end of 1928 there were 188 treatment centres for venereal disease in England and Wales, employing 386 medical officers and with an average of 787 sessions weekly. There was a decrease of 2·7 per cent. in the new cases of syphilis, an increase of 9·9 per cent. in gonorrhœa, and an increase of 10·2 per cent. in patients who attended the centre but were found to be free of venereal disease. The London County Council initiated during the year a scheme for continued observation of girls discharged from hostels. Through the Central Council for the Social Welfare of Girls and Women in London, a certain number of rescue homes have agreed to take in girls who have been under treatment for venereal disease but have become fit to mix with others. This will provide continued treatment and observation for these girls while at the same time enabling the existing hostels to find room for a greater number of acute cases. Experience continues to show that the most important factors in the success of a treatment centre are the personality of the staff and the convenience of the premises. There is a definite improvement in the promptitude with which patients seek treatment, and this is attributed to the steady educational work carried out by local authorities and the British Social Hygiene Council. Expenditure on propaganda is economically justified, for the cost of treatment of a patient whose serum reactions have become positive is at least £2 more than that of a primary case in which the reactions are still negative. Reviewing veneral disease schemes in other countries the Report points out that the British scheme has the advantage of central supervision and universal free treatment.

Food.

An ever-increasing interest is being taken in dietetic questions, and the value of milk for growing children is becoming generally recognised. More than one dairy organisation has inaugurated a scheme for paying farmers a bonus on the bacteriological cleanliness of their milk. The suggestion that "if the public will drink more milk they will get a better, cleaner, and cheaper supply" is characterised as putting the cart before the horse. Not until a better, cleaner, and cheaper supply is provided can increased consumption be expected. There seems no doubt that the cooling of milk at dépôts and its despatch in bulk in suitable tanks is a great improvement, both economically and hygienically. Its only disadvantage is the difficulty which it imposes when any district wishes to trace an infected sample to its origin. The solution seems to lie in the development of a more active control by the authorities of the producing areas. The number of producers and distributors who obtain licences for Certified and Grade A milk is steadily increasing. Of the 12,000 milch cows in licensed herds in 1928, some 4800 were in Certified herds and 7200 in Grade A tuberculin-tested herds. The intradermal tuberculin test has been found the easiest and most reliable under ordinary farm conditions. A large number of samples were taken for bacteriological examination, and most of them were satisfactory. As the Report remarks, the indirect effect of grading is of paramount importance, for it has stimulated the whole industry to produce better milk.

---

[2] THE LANCET, August 17th, p. 348.

Imported meat proved satisfactory during the year, except for some consignments of tuberculous meat from the Irish Free State, and a rather large incidence of caseous lymphadenitis in mutton imported from South America and Australia. The new Food and Drugs (Adulteration) Act came into force on Jan. 1st, 1929, and will simplify the work of those concerned in its administration. Of 120,034 samples of food analysed during the year, 7524 were found adulterated or below standard, and 757 contravened the Preservative Regulations. Nearly half these were sausages or other meat products. The Artificial Cream Act, which came into operation on June 1st, 1929, attempts to regulate the "reconstituted cream," which is prepared by emulsifying butter, dried skim milk and water, and which, if carefully blended, cannot be distinguished from natural cream by the analyst. There were no striking outbreaks of food poisoning during the year, but the Report discusses a number of cases where it was not possible to prove the source of the infection.

Hygiene and International Health.

The Intelligence Section has continued its collection, tabulation, and indexing of medical information from home and foreign sources, and a number of important reports and memoranda were issued during the year. The working arrangement between the Ministry, the Medical Research Council, and the London School of Hygiene and Tropical Medicine has proved satisfactory. During 1928 a great deal of important statistical work was carried out, including investigations into anthropometric data, pre- and neonatal mortality, cancer, certified incapacity, and experimental and clinical epidemiology. The Ministry's pathological laboratory has been paying special attention to the immunological classification of streptococci[3] and a revision of the serological types of the Flexner group.

Rheumatism and Undulant Fever.

The value of the notification of rheumatism remains doubtful. The number of rheumatism supervisory centres is increasing, and the number of beds for the treatment of rheumatic affections under the Metropolitan Asylums Board has increased to 520, in addition to the special unit for 60 acute cases at Carshalton.

Recent investigation has shown that cases of undulant fever occur in European countries where the disease had not been suspected, and the Ministry therefore investigated the possibility of its occurrence in this country. Although it does not appear that there is any endemic undulant fever in England, it is unwise to assume that there never will be, and medical practitioners and bacteriologists are asked to bear the possibility in mind.

Miscellaneous.

Among other inquiries carried out by the Ministry in 1928 was one into the existing provision for sick public-school boys and the principles which should underlie sanatorium accommodation. Another inquiry was made into the supervision which is exercised by local authorities over working conditions in offices. Liverpool seemed to be the only town where offices not associated with workshops undergo any routine inspection. Cubic space, ventilation, lighting, and sanitary accommodation are points of great hygienic importance for office workers, but it must be admitted that detailed systematic inspection of all offices would be extremely onerous, and in the opinion of the Ministry it is doubtful whether the results would justify the time and expense involved. An office committee has considered the hygiene of swimming baths and has laid down certain principles for its maintenance. The Reports on rural water-supplies and artificial light treatment have already been noticed in our columns.[4] The unhappy condition of the coalfields in 1928 led to an inquiry into the conditions of the inhabitants of certain mining areas. The results on the whole were reassuring, apart from an increase in rickets in certain areas of South Wales and a lack of vitality among women, especially expectant and nursing mothers.

THE INTERNATIONAL CONGRESS OF OPHTHALMOLOGY.

MEETING IN HOLLAND.

THE Thirteenth International Congress of Ophthalmology—the first meeting of this nature to take place since the war—was held from Sept. 5th to 13th in Holland. Under the presidency of Prof. J. VAN DER HOEVE the Congress was officially opened by the Queen Mother in Amsterdam, while the concluding sessions were held in the seaside resort of Scheveningen. The meeting was a very large one—larger than any previously held—and the members included the great majority of the leading ophthalmic surgeons from every country in the world; the social arrangements were efficiently and delightfully organised and bore testimony to the boundless hospitality of the Dutch, not the least pleasing aspect being the personal interest shown by the Royal House; and the scientific proceedings throughout were of sustained interest and high standard.

Glaucoma.

The first question for discussion was the Ætiology and Non-operative Treatment of Glaucoma, upon which a symposium was held. It was opened by Duke-Elder (London) who introduced the subject from the physiological point of view. He suggested that in glaucoma the raised tension, although the most obvious symptom, was not the basically essential factor, but was one of the more striking manifestations of a general derangement of the intimate metabolism of the eye. He discussed the economy of the eye in so far as it affected glaucoma under three headings: the equilibrium between the capillary blood plasma and the intraocular fluids; that between the intraocular fluids and the vitreous body; and that between the blood in the choriocapillaris and the retina. He concluded that in the majority of cases glaucoma was ultimately due to an upset of these equilibria determined by changes in the capillaries and changes of a physico-chemical nature in the vitreous body, while the onset of pressure was largely conditioned by a failure in the facilities for drainage at the canal of Schlemm. Hagen (Oslo) followed with a paper wherein he stressed the importance of diurnal variations in pressure; in simple glaucoma the curve generally shows nightly heights, in secondary glaucoma it shows nightly falls. He suggested that the rationale of the first change depended upon obstructed drainage, that of the second on a disturbance in the production of the aqueous humour. Magitot (Paris) started from the principle that glaucoma is essentially an œdema of the eye, the ætiology of which should be associated with the general pathological considerations which produce œdema elsewhere. The chief factor is a derangement of the permeability of the capillary walls, a state determined by disease of the vessels or irritability of the nervous system; general treatment devoted to the whole body is therefore of the first importance. Wessely (Munich) laid stress upon the fact that no theory of glaucoma had yet arrived at the stage when its application could be put to the test of practice, and suggested that it was premature and dangerous to be led away by preconceived theoretical considerations to the subordination of the well-tried local methods of therapy by miotics and operation. He discussed the newer methods of therapy which had been advocated, such as the use of adrenalin, and stressed the danger of allowing the right moment for successful operative intervention to pass through placing unjustifiable reliance upon them. These four opening papers were followed by a prolonged discussion: Passow (Munich) stressed the ætiological importance of the ductless glands, especially an increased function of the thyroid; Fracassi (Arezzo) spoke of the importance of a disturbance of the capillaries either of anatomical or functional nature; Friedenwald (Baltimore) gave a very interesting account of his pathological investigation into the state of the capillaries in acute glaucoma, and described experiments relating these changes to the action of histamine. Hamburger (Berlin) suggested that since glaucoma means a rise of pressure and cyclitis is associated with a fall, the rational treatment of the first disease would be the artificial production of the second. Bonnefon (Bordeaux) discussed the hypotensive action of a retrobulbar injection of adrenalin; in some cases this is due to vasoconstriction, in others to the mechanical pressure effect of the injection. Other papers on glaucoma included a contribution by Sallmann (Vienna) on diurnal pressure curves; by Bistis (Athens) on the influence of the sympathetic nervous system; by Waardenburg (Arnhem) on its association with nævi; by Kerry (Montreal) on the effects of congestion of the ciliary body on the drainage channels of the eye; by Troncoso (New York) on the gonioscope in the diagnosis of glaucoma; by Comberg (Berlin) on the international standardisation of tonometry; by Péretz (Cairo) on the association of glaucoma and cataract; by Jasinski (Poznan) on the osmotic pressure of the blood in glaucoma; by Mawas (Paris) on the hydrogen-ion concentration and the alkali reserve of the aqueous humour; and several contributions to the operative treatment of the disease—those of Tulières (Bordeaux) on sclerectomy; Velter and Duverger (Paris) on the sclerecto-iridectomy of Lagrange; Preziosi (Malta) on the effects of electro-cautery puncture; Meyenhof (Cairo) on sclero-iridotomy; Szymanski (Wilno) on a modification of Elliot's operation; and Fiore (Rome) on a new procedure wherein a sclero-ciliarotomy is made by cautery incision.

[4] THE LANCET, 1928, ii., 1070; 1929, i., 654.

Trachoma.

The second subject chosen for a symposium was the Geographical Distribution and the International Social Campaign Against Trachoma. This attracted a very large number of speakers drawn from all over the world, and, each contributing in statistical form the incidence of trachoma in his own country and the measures which were taken to combat it, an unprecedented review was accumulated which should prove of no small value. Over 25 papers were contributed, but their value can only be appreciated on detailed study; the most impressive result which emerged was the extraordinarily wide geographical distribution of the disease and the immense social and economic disadvantage it brings in its train. In England the incidence of trachoma is low, but in such countries as the Sudan, Palestine, Cochin China, the Argentine, Formosa, and others it is met with in 20 to 30 per cent. of the entire population. The extent of this universal scourge is now generally recognised and measures adopted against it include the control of the frontiers, compulsory notification, examination and treatment of school-children and recruits. It is to be hoped that the result of the wide publicity given to the question in this Congress, and the gathering together of information and the exchange of ideas will lead to a still more intensive world-wide campaign which can do nothing but good.

Suprasellar Tumours.

A third symposium of more than usual interest on the Diagnosis of Suprasellar Tumours was introduced by Christiansen (Copenhagen), Cushing (Boston), Gordon Holmes (London), and Van Bogaert (Antwerp). Christiansen outlined the general symptomatology of these tumours and explained the rationale of the various clinical manifestations, illustrating his remarks by the description of cases. He laid stress on the diminution of the visual acuity, which was usually unilateral and frequently temporal; colour vision alone may be first affected, and a central scotoma was frequent. Cushing omitted from his remarks the more obvious tumours affecting the chiasmal region which were readily recognised by X rays, and confined himself to the simple chiasmal syndrome of optic atrophy and bitemporal field defects produced, in the practical absence of other symptoms, by suprasellar tumours occurring with an approximately normal sella turcica. He discussed the various pathological entities which may be responsible for the condition (adenomata, tumours of Rathke's duct, chiasmal gliomata, meningiomata, &c.), and stressed the importance of distinguishing their early symptoms from toxic amblyopias and retrobulbar inflammatory conditions. Gordon Holmes dealt in detail with the symptomatology of tumours of this region and emphasised several points in their differential diagnosis; he also discussed the clinically related conditions of basal aneurysms which involved the optic pathways, and chronic basal arachnoiditis and the formation of meningeal cysts in the region round the chiasma. Van Bogaert drew a pathological distinction between tumours associated with Rathke's pouch and the other neoplasms in the chiasmal region. He discussed the local symptomatology, and emphasised the systemic derangements which are also met with: somnolence, polyuria, vasomotor, respiratory, and pigmentary disturbances, an upset of the basal metabolism with derangements of carbohydrate, fat, and chloride metabolism, and also psychic effects. He pointed out that these patients usually first applied to the oculist with whom rests the responsibility of diagnosis and the possibility of early treatment. These opening speakers were followed by papers by Brouwer (Amsterdam), who discussed the difference in the visual fields in intra- and suprasellar tumours; by Hirschmann (Berlin) on the diagnostic and therapeutic value of transfrontal pituitary puncture; by Rollet (Lyons) on the clinical forms and complications of suprasellar tumours; by Igersheimer (Frankfurt), Hirsch (Vienna), and others.

Other Subjects.

In addition to these special subjects chosen for symposia a great volume of individual papers was presented, numbering over 250 and ranging over every branch of ophthalmology. The more interesting contributions of a scientific nature included an exposition of the rôle of the rods in the retina in dyscritic vision by Sir John Parsons, who seconded his argument by phylogenetic and recent experimental studies; a paper on the vessels of the iris in reptiles and birds by Mann (London); on the finer structure of the retina with special reference to the corpuscles recently described by Fortin, by Enriquez (Madrid); papers on the lens, with special reference to the iso-electric points of its proteins by Scalinci (Naples), and its mineral constituents by Burdon Copper and Lewis (Bath); and on lens' antigen by Davis (Wisconsin). Interesting cases included one described by Paton and Williamson-Noble (London) of Lindau's disease; the case had come to histological examination and this suggested that the primary lesion is a capillary angioma and that the gliosis is secondary. A somewhat similar case associated with a glioma of the spinal cord was described by Jess (Giessen). Oguchi's disease of the retina and the syndromes associated with congenital hemeralopia was discussed by Oguchi (Nagoya). Cyanosis of the retina in association with vascular disease and polycythæmia was discussed by Moreno (Madrid); arachnodactyly by Ormond (London); retinal melano-epithelioma by Paschoff (Sofia); and many more. Several speakers strongly advocated the treatment of detached retina by ignipuncture, the cautery being inserted through the hole in the retina (if that were present)—Bufill (Barcelona), Gonin (Lausanne), Arruga (Barcelona), and others. The problems of refraction and the prescribing of spectacles, of muscular anomalies and heterophoria, attracted a great deal of attention, and newer methods of operative technique and of treatment, such as by diathermy, provided material for discussion.

Not the least interesting contribution was the demonstration of apparatus and special methods: the gonioscope of Troncoso (New York), the nystagmograph of Ohm (Bottrop), the phoro-optometer stereoscope of Wells (Boston), the ergograph of Berens (New York), the adaptometer of Hertel (Leipzig), the red-free ophthalmoscope of Lauber (Vienna), and others; while a novel and interesting sideline was the demonstration of several films showing ophthalmic operations, particularly by Wessely (Munich) and Elschnig (Prag).

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

Prohibition.

THE event at the recent meeting of the American Medical Association which has given rise to most publicity is one in itself of no particualr importance. Dr. Thayer, the retiring president, let fall some remarks disparaging the present tendency of government to control our personal behaviour. This proved an active stimulus to the chairman of the Methodist Church Board of Temperance, Prohibition, and Public Morals, Rev. Clarence True Wilson, who thereupon launched a violent attack on Dr. Thayer, asserting that he had been unfairly elected to his high office by "wet" influence. This attack was noticed by the House of Delegates, who adopted unanimously a report which stated: "The committee expressly commends and endorses the sentiments expressed by Doctor Thayer concerning legislative enactments that are inimical to the best interests of the medical profession and public by restricting medical men as to what shall, and what shall not, be prescribed for the relief of human ills." Several of the State medical journals, and not least those from the "dry" states, have printed editorials condemning the outburst of this "dry" leader, and extolling the action of the House of Delegates.

Meanwhile, an "open forum" on the subject of prohibition if being conducted by the *Medical Journal and Record*. Letters are printed from doctors in various distant parts of the country, apparently in response to a questionaire. The pros and cons are fairly evenly divided, and the arguments used for the most part, cancel out. Thus the superintendent of a State hospital in Ohio notices "a marked decrease in alcoholic psychoses." The superintendent of a hospital in Michigan is equally positive that the alcoholic psychoses have increased. On this particular point some independent statistical evidence was published last month by H. M. Pollock and F. W. Brown in *Mental Hygiene* (1929, xiii., 591). It appears from their investigations that alcoholic psychoses in 15 States have increased per 100,000 of general population during the years 1921, 1922, 1925, and 1926. The latter rate, however, is slightly less than the corresponding rate for 1919. Data concerning the proportion of intemperate users of alcohol among new admissions were received from 65 hospitals in the 15 States, and show a steady increase in these intemperate users, which is, however, proportionate to the increase in population. The interpretation of all these observations is open to question, since no one can tell what would have happened to the rates if prohibition had not been in force. Whether alcoholism has decreased or not in this country it seems rather obvious that it has not decreased here as rapidly as it has in Great Britain.

Medical Literature and the Mails.

It has been generally assumed that information on contraception cannot be legally put in the mails. Quite recently an article containing such information was offered to the editor of a State medical journal. The article was printed, but only after all the specific instructions as to method had been expurgated. Dr. Dickinson, the energetic secretary of the committee on Maternal Health, now points out that the same law which bans information on contraceptive methods also bans information on the technique of abortion: "every book . . . giving information directly or indirectly . . . by what means . . . any act or operation . . . of any kind . . . for the . . . producing of abortion . . . or how abortion may be performed . . . is declared non-mailable matter." A good many standard text-books must come under this ban. However, it is doubtful whether the law will be enforced against either publisher or recipient in the present state of public opinion. Reports containing details of contraceptive methods, as well as medical journals describing them, have actually been sent through the mails without prosecution having ensued. On the other hand there is no security, and the recipient, as well as the sender, of such literature is liable to a fine of not more than $5000, or imprisonment for not more than five years, or both. The customs authorities rigidly exclude contraceptive apparatus from the country, even when it is addressed to leading hospitals. This has no pronounced effect, since the apparatus is manufactured by several concerns and sold freely at quite reasonable cost within the United States. There are, of course, other means of transportation besides the Federal postal service.

The Prevalence of Venereal Disease.

Recent statistics indicate that the venereal diseases are still widespread in the United States. Among 100,000 male prisoners undergoing routine examination in California a history of venereal sore was obtained from 15 per cent., and in 9·2 per cent. the blood gave a positive Wassermann reaction. Nearly 50 per cent. gave a history of gonorrhœa that could not well be mistaken. Last year in the State of Illinois there were reported 19,826 cases of gonorrhœa and 12,690 cases of syphilis. Among all other diseases pneumonia took first place with 19,130 cases; followed by chicken-pox, 18,081; scarlet fever, 12,855; and tuberculosis, 12,155. Public health authorities tend to rely increasingly on education to prevent the spread of venereal infection. It is reported that some sex instruction is now given in more than 25 per cent. of the high schools of this country, as compared with similar instruction in not more than 10 per cent. of the schools ten years ago.

Tariff Revision.

There has been a good deal of protest against the general upward revision of the Tariff by the House of Representatives in this country, as well as abroad. The proposed increases in the duty on medical and dental instruments (from 45 and 35 to 70 and 60 per cent. ad valorem respectively) caused as much protest as any proposal, and the finance committee of the Senate has tentatively agreed to recommend against the increase. The committee has approved, however, increases in the rates on other instruments and utensils used in hospitals and medical laboratories, and it is to be feared that, unless energetic opposition develops in the Senate itself, a definite increase in the cost of such necessary articles as ophthalmoscopes and hæmocytometers is likely to result from the legislation of the present Congress.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Control of Milk and Meat.

IT is stated that early in the next session of the Dail the Government of the Irish Free State will introduce legislation to control the milk and meat trades in the interests of health. It is believed that in regard to milk two grades will be officially recognised—namely, Grade A (tuberculin tested), and Grade A. For Grade A (tuberculin tested) the milk must be produced from cows which have passed a tuberculin test and have been submitted to veterinary examination. The whole herd must be tested, and every animal to be added to it must be tested before admission to the herd. A veterinary examination is to be made every six months. The milk must not have a bacterial count of more than 100,000 organisms per c.cm., or any coliform organisms in one-tenth c.cm., and must be bottled before distribution. Milk in this grade will be controlled and tested by the Department of Local Government and Public Health. Milk of Grade A must also be bottled before distribution. The herd from which it comes must be submitted to a veterinary examination every three months. The bacterial count must not exceed 200,000 organisms per c.cm., and the milk must not contain any coliform organisms in one-hundredth c.cm. Milk in this grade will be controlled and certified by the local authority. The sale of pasteurised milk will be permitted only in accordance with defined conditions, and the use of misleading terms will be prohibited. Power will be given to a medical officer of health to stop the sale of milk if there is epidemiological evidence that it is the vehicle of infective disease.

The problem of the control of the meat trade is different. Legislation will deal rather with the safeguarding of meat intended for export than with the prevention of disease at home, although, no doubt, both objects are in view. The export trade in fresh meat of all kinds—beef, mutton, pork—has increased nearly fortyfold in the past few years, and the Government is anxious lest this development should be checked by any carelessness about the condition of the meat. Legislation will prohibit the slaughter of animals for export in other than registered slaughterhouses, which must have been inspected to the satisfaction of the Minister before registration. Every slaughter-house will be under the supervision of a veterinary surgeon who will examine all animals before and after slaughter, and he will examine not only the carcasses but the offal. Provision will be made to control methods of transport by road, rail, and sea. The Bill will also deal with the conditions of packing and export of rabbits and poultry.

Conditions of Nursing Service in Cavan.

A recent inspection of the Cavan County Hospital by Dr. Boyd Barrett, one of the inspectors of the Department of Local Government and Public Health, has brought to light the highly unsatisfactory conditions under which the nurses in that institution are expected to work. For a considerable time past there has been discontent among the nursing staff, and many nurses have left after brief periods of service. In his inspection Dr. Barrett found four nurses sharing one bedroom. Another room was given to two nurses, one of whom was on night duty. It was therefore impossible for the nurse on duty to enter the room without disturbing the night nurse. Dr. Barrett found that the time off duty was only two hours a day, which period appeared to have included the dinner-hour. No half-days were allowed, and a whole day was only granted occasionally if work was slack, or to a night nurse after a month's night duty. In this hospital the worst features of the "living-in system," now no longer tolerated by shop-workers, still persist. It is to be hoped that the Department will exercise a careful supervision over the conditions of service of nurses in all institutions under its control.

Recent Appointments in Dublin.

Dr. W. E. J. Jessop has been appointed professor of physiology, physics, and chemistry in the School of the Royal College of Surgeons in Ireland. He has shown exceptional ability as a student in Dublin University, where he is at present assistant to the professor of bacteriology, and has been engaged in research work in chemistry and biochemistry.

Dr. A. G. Thompson has been appointed Rockefeller Foundation Fellow in Biochemistry in Dublin University under the scheme established last year by the Rockefeller Foundation. After a distinguished career in Trinity College, Dr. Thompson last year was appointed director of the pathological laboratory, Jervis-street Hospital.

Public Health Services.

A FATAL CASE OF POST-VACCINAL ENCEPHALITIS.

THE Bridgwater coroner held an inquest on August 27th on a girl of 13, who was vaccinated on August 10th, together with nine other children, all inmates of the Cottage Home at Cannington. Government lymph was used, and four insertions were made. She had not been previously vaccinated, and was in good health. The vaccination ran a normal course, the pustules being well-marked at all four insertions, and the surrounding inflammation quite moderate. On August 21st the girl complained of headache; on the following day she was drowsy, and the temperature rose to 103°F. On August 23rd, on removal to the Isolation Hospital, her temperature was 104°; she was then semi-comatose, with signs of encephalitis. She died at 4.15 P.M. next day without having recovered consciousness. Dr. G. W. Harvey Bird, medical officer of health for Bridgwater, tells us that the post-mortem examination, carried out the same night, revealed no sign of disease in chest or abdomen. There was no meningitis, but the entire brain was congested. None of the other nine children vaccinated developed untoward symptoms. Dr. Bird remarks that the incubation period of 11 days is apparently typical of post-vaccinal encephalitis.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED SEPT. 7TH, 1929.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 150 (last week 131); scarlet fever, 1964; diphtheria, 884; enteric fever, 107; pneumonia, 538; puerperal fever, 56; puerperal pyrexia, 94; cerebro-spinal fever, 8; acute poliomyelitis, 21; acute polio-encephalitis, 0; encephalitis lethargica, 20; dysentery, 9; ophthalmia neonatorum, 105. No case of cholera, plague, or typhus fever was notified during the week.

The number of case in the Infectious Hospitals of the Metropolitan Asylums Board on Sept. 10th–11th was as follows:—Small-pox, 150 under treatment, 14 under observation (last week 165 and 8 respectively); scarlet fever, 1837; diphtheria, 1456; enteric fever, 18; measles, 277; whooping-cough, 218; puerperal fever, 23 (plus 8 babies); encephalitis lethargica, 125; poliomyelitis, 2; "other diseases," 28. At

St. Margaret's Hospital there were 15 babies (plus 8 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 4 (2) from enteric fever, 15 (2) from measles, 5 (0) from scarlet fever, 25 (6) from whooping-cough, 14 (2) from diphtheria, 79 (15) from diarrhœa and enteritis under two years, and 15 (2) from influenza. The figures in parentheses are those for London itself.

Of the deaths from diarrhœa (the number of which is practically stationary), 8 were reported from Liverpool, 7 from Birmingham, 6 from Gateshead, 4 from Sunderland, and 3 each from Leeds and Hull. Glasgow, Dublin, and Belfast reported 7, 0, and 4, respectively. Deaths from measles were reported from Liverpool and Sunderland, 3 each. Both fatal cases of enteric fever occurred at Birmingham.

The number of stillbirths notified during the week was 240 (corresponding to a rate of 37 per 1000 births), including 48 in London.

Obituary.

CHARLES ALEXANDER MORTON, O.B.E., F.R.C.S. ENG.

THE death of Mr. C. A. Morton which occurred, as *briefly announced on Sept. 14th, during a holiday in* Switzerland, ends a long and useful surgical career. Charles Alexander Morton was born in Bristol in 1860, his father John Morton himself being a surgeon, at one time on the staff of the East India Company in the Madras Presidency. He was educated at Clifton and went on to St. Bartholomew's Hospital for his clinical work, when he took prizes at every stage of his course, ending with the coveted Brackenbury Medical Scholarship. After qualifying in 1881 he became house surgeon at the Stanley Hospital in Liverpool, returning in the next year to be house physician at St. Bart.'s. In the period that followed he continued to gain varied experience in resident appointments, including that of house surgeon at the Cumberland Infirmary, resident medical officer at the Manchester Children's Hospital, clinical assistant at Great Ormond-street, and resident clinical assistant at the Leicester Infirmary. *At this time* he frequently contributed to current medical literature, his interests covering such subjects as subacute anterior spinal paralysis, coal gas and carbolic acid poisoning, ruptured hydatid cyst of the liver, and intestinal obstruction. Returning to Clifton he took the F.R.C.S. Eng., and became in 1891 registrar to the Bristol General Hospital, and assistant surgeon two years later; for 27 years was on the surgical staff of the hospital, retiring as senior surgeon in 1920. For 25 years he was also surgeon to the Bristol Children's Hospital, and he had surgical charge *at the Cossham Memorial* Hospital. These appointments were a matter of course, for Morton was, with the exception of Greig Smith, the first man of the Bristol school to devote himself purely to surgery.

PROF. MORTON.

Morton's work as a surgical teacher began with his appointment as professor of surgery in University College, Bristol, in 1897, and he occupied the chair for 28 years until his resignation in 1925, when he was appointed emeritus. As a teacher of students he was acutely aware of the contradictory nature of many of the statements contained in the current text-books, and he put forward a scheme for the production of a standard text-book of surgery for use by examiners and examinees alike. The objection that such standardisation might stifle inquiry he met with arguments to the contrary that impressed if they did not convince his fellow-teachers. As a surgeon he spared no effort in diagnosis, and demonstrated to students in the wards with emphasis which omitted no pathological possibility from consideration. He prepared the patient's skin for an operation with a thoroughness that amounted almost to a fault, operated and closed the wound with great deliberation, relying on others to the minimum, and doing his own dressings with a ritual that was nearly as precise as that of his operations. Such a laborious and painstaking performance may sometimes have been tedious to fellow workers, but it led to results which compelled the respect of the surgical profession and the warm admiration of his dressers, and earned the deep gratitude of his patients. During the war his work at the Beaufort (Territorial) Hospital was specially responsible and onerous. His interest then centred round injuries of nerves and blood-vessels, but he remained all his life at heart a general surgeon in the widest sense, and his contributions to surgical literature cover a large field. Two of these, on cuneiform osteotomy of the tibia for genu valgum and on the end-results of the surgery of cancer of the breast, are typical of his sound style and reasoning.

A man of strong individuality Morton took some part in public life and on committees of various kinds he showed an independence of thought which led him along well-reasoned lines to many valid conclusions. The critical faculty so dominated him that it often led him to assume opposition, as if his fellows could never be on the side of wisdom and truth, but at no time in his career did anyone, whether in agreement or disagreement with him, question either his sincerity or his singleness of heart. After retiring from hospital work he served as a member of the board of guardians, and here again he was concerned with the wider issues of administration. In politics his careful and analytical mind led him to support a non-partisan policy. Always of a retiring disposition Morton was latterly rather a lonely figure in Bristol. He was never physically robust, and he was unable to keep up the cycling and walking that had always served him as sole recreation in his more strenuous years. But many scores of patients will thankfully remember the unstinted services in which his life was spent.

Charles Morton was unmarried. His elder brother, Mr. Stanford Morton, the ophthalmologist, who lived in Clifton after his retirement, predeceased him by two years.

ST. GEORGE'S HOSPITAL.—The annual report of the House Committee calls attention to the enormous increase in the cost of maintenance. Last year it was £88,916, which is more than double the expenditure in 1913; the adverse balance was £7016. It is stated that every economy consistent with the proper treatment of the patients has been continuously practised, but unless an additional income of at least £20,000 can be secured "the time cannot fail to arrive when it may become necessary to curtail the hospital's activities." In 1928 there were 6000 in-patients, who stayed on the average 22 days and cost £14 10s. each. There were 30,705 new out-patients who cost about 7s. each. Contributions by, or on behalf of, patients amounted to £18,561.

THE "GRADING" OF BREAST CARCINOMATA.

To the Editor of THE LANCET.

SIR,—No one appreciates more than I the admirable work which Mr. D. H. Patey and Dr. R. W. Scarff have undertaken to divide carcinomata of the breast into different grades of malignancy. Their task is difficult and none would be justified in disparaging their careful methods of observation. At the moment all I wish to point out is that the primary tumour in carcinoma of the breast is the epithelial neoplasia that exists within the normal boundaries of ducts and acini and from which the invading cells originated. All epithelial cells that have transgressed those boundaries and are multiplying in outside tissues have an equal claim to be regarded as "secondary deposits," whether or no they have reached lymphatic glands. From this point of view—and it appears to me to be the correct one—the lump that forms the compact mass in the breast and which is generally spoken of as being the "primary tumour" is composed of "secondary deposits" and the primary tumour situated in the ducts and acini. When suitable methods are adopted the initial primary tumour—viz., the epithelial neoplasia—in the ducts and acini can be detected in all examples of early carcinoma of the breast without exception. In the later stages the detection is not so easy and in many instances the primary lesions are obliterated by the welter of secondary epithelial cell invasion. In attempting to grade the degree of malignancy in carcinoma of the breast the morphological and biological characteristics of the epithelial neoplasia within ducts and acini forms the most instructive and accurate standard on which to base comparisons between it and all its epithelial descendants.—I am, Sir, yours faithfully,

G. LENTHAL CHEATLE.

Harley-street, W., Sept. 12th, 1929.

THE "ASUERO" TREATMENT

To the Editor of THE LANCET.

SIR,—In the spring of this year the reports in the lay press of cures of paralysis by the Asuero method of treatment led to inquiries from patients suffering from different forms of paralysis whether they ought to risk the adventure of foreign travel to obtain this treatment or whether it could be applied in this country. I have recently had an opportunity of meeting in Lisbon a Dr. Patacho, who had just returned from a course of instruction in San Sebastian under Dr. Asuero, who is an ear, nose, and throat surgeon at the Red Cross Hospital. The line of treatment associated with his name evidently consists in setting up a reflex action through the mucous membrane of the nose. With a blunt probe shaped in a peculiar manner he searches for a sensitive spot —usually found in the mucous membrane covering the inferior or middle turbinate bones. This spot is not a fixed one, and is detected by the fact that every slight touch on it is sufficient to cause lacrymation and dilatation of the pupils. When the spot has been found it is treated by another blunt instrument which has been previously warmed; only occasionally is this instrument made hot. Most of the reports of the treatment have come from Lisbon, and I was content to make that city the centre of my investigations. I came to the conclusion that the people of Portugal are a more impressionable people than we are, and that no blame could be attributed to Asuero or his trained assistants for the sensational accounts of the cures obtained, though these are grossly exaggerated.

The following list of diseases from one of Asuero's printed cards shows the varied conditions which he claims to have treated with benefit: glycosuria, varicose ulcers, rheumatism in all its manifestations, hæmorrhoids, menstrual conditions, all pains, headache, noises in the ear, vertigo, pyorrhœa, epilepsy. Dr. Patacho did not entirely agree with this list, and it is hardly necessary to emphasise the fact that Asuero makes no mention of paralysis. In anterior poliomyelitis Dr. Patacho had failed to produce any results. The treatment is always used in conjunction with other known medical measures.

Whether any of the types enumerated by Asuero are really benefited is uncertain, but meantime it may be a service to my colleagues to have further confirmation of what they already must have guessed. Patients and their friends may rest assured that miracles are not being performed, and no case of paralysis with destruction of nerve or muscle tissue need hope for cure by such a method. On the other hand, it may be that in functional cases a strong reflex stimulation will suddenly rearrange the disordered cycle of impulses and lead to a restoration of voluntary activity, but the patient may rely on his family physician to know whether he falls into that category. An electrical test will soon reveal the condition and, if nerve conduction is intact, results of a startling nature may often be obtained quite apart from Asuero treatment. I am, Sir, yours faithfully,

THOMAS MARLIN.

Park-crescent, W., Sept. 16th, 1929.

*** This account confirms the impression conveyed by the note on this treatment from Dr. A. G. Gray, of Madrid, published in THE LANCET of June 15th, p. 1284.—ED. L.

OCCUPATIONAL DISEASES OF HOP-PICKING.

To the Editor of THE LANCET.

SIR,—The paper by Dr. Beatrice M. Smithies in your issue of Sept. 7th (p. 494) is of great interest to any practitioner who, like myself, works in a hop-growing district. Every year one comes across the three conditions she describes so clearly. With regard to the third, "hop gout," I am inclined to think the terminology is misleading. All the cases I have met with have differed in no way from typical tenosynovitis. Naturally this is unilateral, as the movements of the two hands in hop-picking are different; one hand is used for holding and the other for picking. Occasionally true gout occurs among hop-driers, but this is a totally different condition from that described by Dr. Smithies, and arises from quite different causes.—I am, Sir, yours faithfully,

Ledbury, Sept. 12th, 1929. LESLIE B. C. TROTTER.

IS CHILDBIRTH EASY AMONG PRIMITIVE PEOPLES?

To the Editor of THE LANCET.

SIR,—In an annotation on the Infancy of Midwifery in THE LANCET of April 6th (p. 727) I read that "among primitive peoples childbearing is often so easy as hardly to disturb the mother's working life." I was, Sir, of that opinion until I came to this island of the South Pacific (lat. 7° south), where I am the first medical man to be stationed.

These people are certainly primitive. The practice of head-hunting ceased only six years ago, and many men still carry their axes or spears and shields. Within the last fortnight, and only a mile distant, for no very apparent reason, a man killed his wife and child and burnt the hut over them. Spirit-worship is prevalent and fear of evil spirits is deeply inbred in the lives of the people. The women support the family by work in the gardens and carry their heavy loads home at night usually two to four miles over rough and hilly ground. When his wife is near full term the husband builds a leaf hut in the bush. This is the nursing home where she must stay until 14 days after the birth of the child. She sits on a log, her back supported by the knees of a woman sitting behind. Another woman presses on the fundus.

But childbearing under these conditions is by no means a minor event to the woman and not rarely the leaf hut witnesses the death of the mother or child or both. The last six consecutive cases admitted to this hospital support this view.

1. Second pregnancy. Last baby born dead. This time two and a half days' labour; pains increasing in strength and severity. Forceps. Puerperium: cystitis.
2. First labour difficult. Baby born dead. This labour: small pains 12 hours, severe 30 hours. Puerperium: obstinate cough.
3. Primipara. Labour 18 hours, strong pains. Puerperium: breast induration with fever.
4. Multipara. Labour 12 hours; strong pains.
5. Multipara. *Last labour, uterus "came right outside."* Vulva showed old tear of second degree. This labour: 16 hours, severe pains. Puerperium: severe perisplenitis of enlarged spleen (malaria).
6. Primipara. Small pains, increasing in severity. Waters broke after 48 hours. Severe pains for further 24 hours.

Further confirmation is supplied by the frequently heard statement "his mother died when he was born." I am not dealing with causes. I wish only to state that here, at least, amongst this primitive people with all its disease, dirt, and customs which go to make up the picture, labour is not a minor incident, and would seem to be no whit easier than in New Zealand or Dublin.

I am, Sir, yours faithfully,

CLIFFORD JAMES, M.B. (N.Z.), D.T.M. & H. (Lond.), F.R.C.S. Edin.

Methodist Mission Hospital, Choiseul, British Solomons,
July 24th, 1929.

EFFECT OF X RAYS ON BLOOD-PLATELETS.

To the Editor of THE LANCET.

SIR,—We are certain that Dr. Cramer and Dr. Mottram need no assurance from us that we had no intention of misrepresenting their results, or of detracting in any way from the value of their work. The important points to us appear to be: (1) What are the changes produced by radiation on the blood-platelets? (2) What relation, if any, do they bear to the symptoms of radiation sickness? (3) Is the cat a suitable animal for blood-platelet studies?

Our experiments show that the decline in the platelet count in the cat is not associated with evidence of infection, and does not seem to run parallel with the deterioration in the clinical condition; in fact, signs of general improvement are visible before the platelets are at their lowest level, and the animal may appear outwardly quite normal long before full recovery of the platelets to their original level has taken place. Animals that succumbed with marked evidence of infection showed no significant change in the platelet count; in the experiments of Cramer, Drew and Mottram, the animals that died of infection also showed a thrombopenia. It was this difference between our results and theirs that we wished to draw attention to, especially in view of the fact that Dr. Cramer and his co-workers have in a number of communications laid stress on the frequent association of infective states with thrombopenia.

We incline to the view that the infective conditions which are so striking a feature following lethal doses of X radiation in the cat may be due to injury to the small intestine (of which we have ample evidence), coupled with the almost complete disappearance of the white cells from the blood. Dr. Cramer has reported changes in the intestine following gamma radiation, though they do not appear to be altogether of the same nature as those observed by ourselves following X radiation.

Dr. Cramer and Dr. Mottram further suggest that the cat may be an unsuitable animal for blood-platelet studies. We think that it is always advisable to work with an animal which is as high up the scale as possible, if one hopes to draw any conclusions which may be applicable to man. The statement in our paper that "the range of normal variation noted in the small series studied is from 0·75 million to over 5 millions," meant, of course, that this was the range noted in the series and not in any one individual. In fact, cats can be divided into two groups from this point of view: those with high and those with low platelet counts. Animals with high platelet counts continue to show this feature if regularly examined over a period of weeks, and such animals appear to us peculiarly suitable for radiation studies for this reason. The criticism frequently offered on platelet work in the past has been that the variations produced are not strikingly outside the range of error of the technique; we feel that this objection cannot be offered against results such as ours, in which the platelet decline was from the order of several millions to one of several hundred thousands per cubic millimetre.

We are, Sir, yours faithfully,

SAMSON WRIGHT.

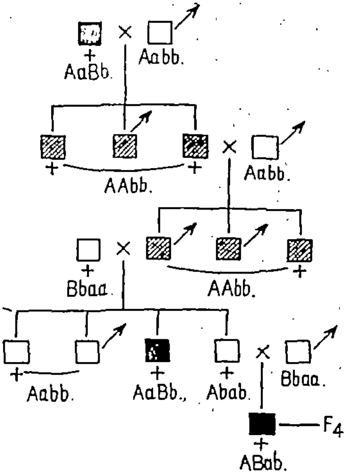
AN INHERITED TENDENCY TO SUPERNUMERARY DIGITS.

To the Editor of THE LANCET.

SIR,—"*Phalanx's*" *letter in your issue of August 3rd* (p. 256) affords some more data with regard to the complicated story of polydactylism. There exists a mass of apparently conflicting evidence in cats, guinea-pigs, and poultry. The matter is not at all clear yet and the following hypothesis, which accounts for the pedigree cited by "Phalanx," must not be considered to be necessarily correct. I suppose that the supernumerary digits are the result of the interaction of two Mendelian factors (A) and (B); while when one factor (A) is present in the homozygous condition it produces the long thumbs, like index-fingers. In the accompanying chart I have set out the pedigree given by "Phalanx," the black signs representing persons with supernumerary digits and the shaded signs those with long thumbs. On this hypothesis it is seen that any of the F_4 children are liable to have supernumerary digits.



I am, Sir, yours faithfully,

HUMPHREY J. H. HARE, M.A.

Great Yarmouth, Sept. 3rd, 1929.

Medical News.

DEATH OF DR. R. T. SLINGER.—The death of Robert Townley Slinger, M.B. Manch., F.R.C.S. Eng., on Sept. 10th, at the early age of 49, is deeply regretted in Worcester, where he was in general practice for 20 years. An honours graduate of Owens College, he qualified in 1903, and began a series of appointments at the Manchester Children's Hospital and the Royal Infirmary. In 1906 he collaborated with Sir Victor Horsley in a paper on the Orientation of Points in Space by the Muscular, Arthrodial, and Tactile Senses of the Upper Limbs, and two years later he took the diploma of F.R.C.S. Dr. Slinger went to Worcester in 1909 as a partner of the late Dr. T. P. Gostling, and when the latter retired he undertook single-handed the work of a general practice which was continually expanding. His services were early sought for the Worcester Infirmary, and he became at first anæsthetist and then hon. surgeon. He gave of his best to his patients here in skill and in time. Despite the calls of a big practice, he always regarded the infirmary as his first duty. His surgical technique was of a high order, and he successfully undertook operations requiring much experience and judgment. His colleagues and patients in Worcester were about to present him with a testimonial in token of their regard, and to show their sympathy with him in his misfortune at having to give up practice owing to bad health. Unfortunately, the presentation never took place, owing to the rapidity of his last illness. The fund is still open for those who would show in a practical way their gratitude for kindnesses received. He leaves a widow.

ROYAL INSTITUTE OF PUBLIC HEALTH.—A course of lectures on Problems of Personal and Public Health will be given at this Institute, 37, Russell-square, London, W.C. on Wednesdays, at 4 P.M., from Oct. 16th. The lecturers will be Dr. Graham Little, on the Health and Conditions of Work of Medical Students (Oct. 16th); Mr. J. C. Stobart, on Broadcasting and Health (Oct. 23rd); Dr. A. F. Hurst, on the Asthma Problem (Oct. 30th); Mr. Stanford Cade, on the Possibilities and Limitations of Radium Treatment (Nov. 6th); Dame Louise McIlroy, on the Influence of Pathology upon Maternal Welfare (Nov. 13th); Dr. Malcolm Donaldson, on the Early Diagnosis and Treatment of Malignant Disease (Nov. 20th); Prof. Lyle Cummins, on Some Aspects of the Tuberculosis Problem (Nov. 27th); Dr. Alfred Jordan, on Dress in Relation to Health and Disease (Dec. 4th); Prof. Winifred Cullis, on Speed as a Psychophysiological Factor in the Life of To-day (Dec. 11th); and Prof. E. L. Collis, on Industry in Relation to Personal and Public Health (Dec. 18th).

The *Harben Lectures* will be given at the same place at 5 P.M. on Fridays, Oct. 18th and 25th, and Nov. 1st, by Dr. R. A. Peters, Whitley Professor of Biochemistry in the University of Oxford. His subject is the Coördinative Biochemistry of the Cell and Tissues.

MANCHESTER ROYAL INFIRMARY: *Post-graduate Courses.*—From Sept. 24th post-graduate lectures and demonstrations at the Royal Infirmary will be held weekly, at 4.15 P.M. on Tuesdays, until Dec. 10th, after which they will be resumed in March. Besides these lectures, there will be others on special subjects, from Friday, Sept. 27th, onwards. Particulars will be found each week in our Medical Diary.

The *Lloyd Roberts Lecture* will be given this year on Wednesday, Nov. 27th, at St. Mary's Hospital, Whitworth-street West, by Mr. Comyns Berkeley, who will speak on the Teaching of Obstetrics and Gynæcology.

HOSPITAL SATURDAY FUND.—The annual collection for the Hospital Saturday Fund will be taken on Sept. 28th, and Lord Burnham, the treasurer, has issued a special appeal in which he calls attention to the fact that the demands of medical science make it imperative that additional support should be given to our hospitals to enable them to take full advantage of the knowledge available for combating disease, and expresses the hope that the public will respond generously. Offers of help should be made to the Secretary of the Fund, 52–54, Gray's Inn-road, London, W.C.1.

A HOME FOR CRIPPLED CHILDREN.—Viscountess Feilding last week opened the Paybody Convalescent Home for Crippled Children at Allesley, near Coventry. A house known as The Elms was presented to the Coventry and District Crippled Children's Guild by Mr. Thomas Paybody, of Coventry, who subsequently gave £2000 in memory of his son towards the cost of adaptation. There are 750 crippled children on the books of the guild.

ROYAL NORTHERN HOSPITAL POST-GRADUATE COURSES.—A course of lectures or lecture-demonstrations on Children's Diseases, for practitioners and others, will be given at the Royal Northern Hospital from Oct. 14th to 22nd, lectures being delivered daily at 2.30 P.M., Saturday and Sunday excepted. Further particulars may be had from the Dean of the hospital, Holloway-road, London, N.7.

POST-GRADUATE COURSES IN BERLIN.—A series of special post-graduate courses will be held in Berlin during October. Particulars of these, and of courses held regularly through the year, may be had from the information bureau of the Kaiserin Friedrich-Haus für das ärztliche Fortbildungswesen, Luisenplatz 2–4, Berlin, N.W.6, which can also arrange for attendance at clinics and accommodation in lodgings.

EPSOM COLLEGE.—A vacancy has arisen for a Salomons Entrance Scholarship of £50 a year. Candidates must be sons of legally qualified members of the medical profession either living or deceased, and only those may apply who were over 11 years and under 14 years of age on Jan. 1st last. The regulations provide that the candidate must show an adequate standard of education for his age, and that his financial condition is such as to make it impossible or difficult to obtain an education at the College without the help of the scholarship. Applications must be sent by Sept. 30th to the Secretary of the College, 49, Bedford-square, W.C.1, from whom the requisite forms can be obtained.

NORTH PERSIAN FORCES MEMORIAL MEDAL.—Dr. G. Stuart, Colonial Medical Services, has been awarded the North Persian Forces Memorial Medal for the year 1928 for his paper, the Serological Diagnosis of the Enterica by the Method of Qualitative Receptor Analysis, written in conjunction with Dr. K. S. Krikorian, and published in the *Journal of Hygiene*, Nov. 26th, 1928, vol. xxviii., No. 2, pp. 105–126. This medal is awarded annually for the best paper on tropical medicine or hygiene published in any journal during the preceding 12 months by a medical officer, of under 12 years' service, of the Royal Navy, Royal Army Medical Corps, Royal Air Force, Indian Medical Service, or of the Colonial Medical Service.

NEW TROWBRIDGE HOSPITAL.—The Marquess of Bath last week opened a new hospital in place of the old inadequate one, which has been sold to the Wiltshire County Council for use as a clinic. The nucleus of the institution is Adcroft House, a large private residence which has been converted into an administrative block; new buildings, all on the ground floor, have been added on each side. On one side are a men's ward of eight beds, three private wards for men, and a children's ward of six beds. On the other side are women's wards of somewhat similar accommodation, including a maternity ward of six beds. In the operating block are an X ray room, and the usual appurtenances. The cost has been about £10,000.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Sept. 23rd, to SATURDAY, Sept. 28th.—WESTMINSTER HOSPITAL. Special all-day course in medicine, surgery, and the specialties. 10.30 A.M. to 5.30 P.M. daily.—BETHLEM ROYAL HOSPITAL, S.E. Post-graduate course in psychological medicine. Tues. and Sat. at 11 A.M.—Further particulars from the Fellowship of Medicine.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, Sept. 23rd.—2.30 to 5 P.M.: Medical, Surgical and Gynæcological Clinics. Operations.

TUESDAY.—2.30 to 5 P.M.: Medical, Surgical, Ear, Nose and Throat Clinics. Operations.

WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin, and Eye Clinics. Operations.

THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, Nose, Throat, and Ear Clinics. Operations.

FRIDAY.—10.30 A.M.: Throat, Nose and Ear Clinics. 2.30 to 5 P.M.: Surgical, Medical, and Children's Diseases Clinics. Operations.

CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL, Gray's Inn-road, W.C.

MONDAY, Sept. 23rd.—1.30 P.M., Examination and Diagnosis of the Ear.

WEDNESDAY.—1.30 P.M., Examination and Diagnosis of the Nose.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE.

TUESDAY, Sept. 24th.—4.15 P.M., Mr. J. P. Buckley: Some points relating to the Ætiology and Treatment of Appendicitis.

FRIDAY.—4.15 P.M., Dr. Catherine Chisholm: The Treatment and Development of the Premature and Immature Infant.

Appointments.

LITTLE, R. H., M.B., B.S. Lond., has been appointed Certifying Surgeon under the Factory and Workshop Acts for the Ringwood District of the County of Southampton.

MCCURRACH, ELIZABETH G., M.B., Ch.B. Aberd., D.P.H., Assistant Medical Officer of Health for Aberdeen.

Westminster Hospital: KENDALL, A. W., M.B., B.S. Lond., Senior Resident and Casualty Officer; HUTTON, A. E., L.R.C.P. Lond., M.R.C.S., Resident House Physician; CAUDWELL, C. E., L.R.C.P. Lond., M.R.C.S., Resident House Surgeon; TOLAND, C. P. K., L.R.C.P. Lond., M.R.C.S., Resident House Physician; MORGAN, J., M.B., B.S. Lond., Resident Obstetric Assistant and House Physician to the Children's Department.

Vacancies.

For further information refer to the advertisement columns.

Aberystwyth Infirmary and Cardiganshire General Hospital.—H.S. £200.

Albert Dock Hospital, Connaught-road E.—Surgeon.

Aylesbury, Royal Buckinghamshire Hospital.—Res. M.O. At rate of £180.

Barrow-in-Furness County Borough.—Asst. M.O.H. and Asst. Tub. O. £600.

Bath, Royal United Hospital.—H.S. At rate of £150.

Bedford County Hospital.—Asst. H.S. At rate of £130.

Belgrave Hospital for Children, 1, Clapham-road, S.W.—H.S. Also Asst. H.P. Each at rate of £100.

Birkenhead General Hospital.—Cas. S. £100.

Birmingham General Hospital.—Two Res. Anæsthetists. Each £120. Also three H.S.'s. Each £70.

Birmingham, Selly Oak Hospital.—Res. Physician. £100–£600.

Blackburn and East Lancashire Royal Infirmary.—Fourth H.S. £130.

Bournemouth, Royal Victoria and West Hants Hospital.—H.S. At rate of £120.

Bradford, Royal Eye and Ear Hospital.—Jun. H.S. £120.

Brighton, Royal Sussex County Hospital.—H.P. £150.

Bristol City and County Mental Hospital.—2nd Asst. M.O. £500. Also 3rd Asst. M.O. £350.

Cape Town University.—Asst. Anatomist. £750.

Chester Royal Infirmary.—H.S. £120.

City of London Hospital for Diseases of the Heart and Lungs, Victoria Park, E.—H.P. At rate of £100.

Coventry City.—M.O.H. £1225.

Epsom, Surrey, Norton Mental Hospital.—Fourth Asst. M.O. £425.

Exeter, Royal Devon and Exeter Hospital.—Hon. Physician.

Evelina Hospital for Children, Southwark, S.E.—H.S. At rate of £120.

Federated Malay States, Central Health Board.—Three M.O.'s for Estate Service. Each at rate of £980.

Godalming, King George V. Sanatorium.—Jun. Asst. M.O. £500.

Golden-square Throat, Nose, and Ear Hospital, W.—Registrar. Also Hon. Anæsthetist.

Gloucester, Gloucestershire Royal Infirmary, &c.—Hon. S. to Ear, Nose and Throat Dept. Also First H.S. At rate of £135.

Great Yarmouth General Hospital.—Sen. H.S. £150.

Grosvenor Hospital for Women, Vincent-square, S.W.—Res. M.O. At rate of £100.

Guy's Hospital.—Astley Cooper Studentship.

Hampstead Parish of St. John, New End Hospital.—Jun. Res. Asst. M.O. At rate of £200.

Hospital for Sick Children, Great Ormond-street, W.C.—Asst. Path. and Research Fellow. £450. Also H.S. and H.P. Each at rate of £100.

Hospital of St. John and St. Elizabeth, Grove End-road, N.W.—Res. H.S. At rate of £75.

Hull Royal Infirmary.—Asst. H.P. At rate of £130.

Isleworth, West Middlesex Hospital.—Res. Asst. Med. Supt. and Asst. M.O. £450.

Lewisham Metropolitan Borough.—Asst. M.O.H. and Maternity and Child Welfare M.O. £650.

Liverpool, David Lewis Northern Hospital.—Res. H.S. and Res. H.P. Each at rate of £100.

Liverpool, Royal Southern Hospital.—Medical Tutor and Registrar.

London Homœopathic Hospital, Great Ormond-street, W.C.—Asst. Surg. for Dis. of Eye.

London Hospital, E.—First Asst. and Registrar. £300.

London Jewish Hospital, Stepney Green, E.—Hon. Asst. S. for Gynæcological Dept., Hon. Asst. Radiologist. Also Hon. M.O. for Actino-Therapeutic Dept.

London Lock Hospital, 91, Dean-street, W.—H.S. At rate of £200.

London Temperance Hospital, Hampstead-road, N.W.—Res. M.O. At rate of £175.

Manchester Babies' Hospital, Burnage-lane, Levenshulme.—Jun. Res. M.O. At rate of £50.

Manchester Ear Hospital, Grosvenor-square, All Saints.—H.S. At rate of £150.

Manchester, Salford Royal Hospital.—Two H.S.'s. Also Cas. H.S. Each at rate of £125.

Margate, Royal Sea Bathing Hospital.—H.S. At rate of £100.

Maudsley Hospital, Denmark Hill, S.E.—Asst. M.O. £300.

Mildmay Mission Hospital, Austin-street, Bethnal Green, E.—Jun. Res. M.O. Also Asst. Cas. O. Each at rate of £100.

National Dental Hospital, Gt. Portland-street, W.—Hon. Anæsthetist.

Northampton, Northamptonshire County Council.—M.O.H. and School M.O. £1,100.

North Middlesex Hospital, Silver-street, Edmonton, N.—Res. M.O. £200.

Norwich, Norfolk and Norwich Hospital.—H.S. £120.

Nottingham Children's Hospital.—Res. H.P. At rate of £150.

Poole, Cornelia and East Dorset Hospital.—H.S. At rate of £150

Prince of Wales's General Hospital, Tottenham, N.—Sen. H.P. Sen. H.S., and Special H.S. Each at rate of £120. Also Jun. H.P., and Two Jun. H.S.'s. Each at rate of £90.

Princess Louise Kensington Hospital for Children, North Kensington.—H.P. At rate of £75.

Queen's Hospital for Children, Hackney-road, E.—H.P. Also Cas. O. Each at rate of £100.

Queen Mary's Hospital for the East End, E.—Anæsthetist for the Dental Dept. £25.

Rotherham Hospital.—H.P. £180.

Royal Free Hospital, Gray's Inn-road, W.C.—Sen. Res. M.O. £150. Also Cas. O. £150.

Southampton, Royal South Hants and Southampton Hospital.—Cas. O. At rate of £120.

Stafford, County Mental Hospital.—Second Asst. M.O. £600.

Stockport County Borough.—Clin. Tub. O. and Sen. Asst. M.O.H. £750.

Stockton-on-Tees, Stockton and Thornaby Hospital.—Jun. Res. M.O. £150.

Sudan Medical Service.—M.O. £E720.

Swansea Hospital.—H.S. £150.

West London Hospital, Hammersmith, W.—Hon. Registrar for Throat, Nose, and Ear Dept. Also House Officer for Children's Dept. At rate of £150.

Births, Marriages, and Deaths.

BIRTHS.

ARCHER.—On Sept. 11th, at York-place Nursing Home, to Frances, wife of Dr. G. E. Archer, of Victoria Park, Manchester, the gift of a son.

LINDSAY.—On Sept. 11th, at 47, Harefield-road, Brockley, the wife of Sidney S. Lindsay, M.B., B.S., M.R.C.S., of a daughter.

LONGFORD.—On Sept. 12th, the wife of Dr. W. U. D. Longford, Holywood, County Down, Ireland, of a son.

ROLLES.—On Sept. 14th, at Fitzjohn's Avenue, Hampstead, the wife of Francis C. Rolles, M.A., M.R.C.P., of a daughter.

SHAW.—On Sept. 11th, at Trafalgar-lawn, Barnstaple, N. Devon, the wife of Dr. S. C. Shaw, of a son.

WAKELY.—On Sept. 9th, at Carshalton, the wife of Dr. A. S. Wakely, of a son.

WHITTINGTON.—On Sept. 9th, at Oakfield, Sutton, Surrey, the wife of Theodore H. Whittington, M.D., of a son.

MARRIAGES.

ELGOOD—FRANCIS.—On Sept. 9th, at St. Martin-in-the-Fields, London, John Elgood, M.B., F.R.C.S., to Christine Phyllis Francis, M.B., B.S., elder daughter of Mr. and Mrs. J. E. Francis, of the Athenæum Press, London.

FLIND—RUSSELL SMITH.—On Sept. 10th, at St. Michael's Church, Highgate, James Flind, M.B., B.Ch., D.P.M., to Joan, younger daughter of Mr. and Mrs. Russell Smith, of Moorhaven, Stormont-road, Highgate.

WESTLAKE—BROWN.—On Sept. 9th, at the Wesleyan Church, Deal, Henry John William Jennings Westlake, B.Sc., M.R.C.S., L.R.C.P., to Evelyn Crosdee, only daughter of Mr. H. G. Brown, Solicitor, and Mrs. Brown, of Melsonby, Grange-road, Deal.

DEATHS.

BLUNT.—On Sept. 12th, at Linden Villas, Westfield-road, Wakefield, Henry Brine Blunt, M.B., C.M., aged 70 years.

GIFFARD.—On Sept. 15th, at a nursing home in Bournemouth, Douglas William Giffard, M.R.C.S. Eng., L.S.A., formerly of Brighton, aged 81 years.

HARRIS.—On Sept. 6th, at Hartwood House, Chorley, Lancashire, James Alfred Harris, M.D.

MARSHALL.—On Sept. 10th, at Inglewood, Eldorado-road, Cheltenham, Dr. Lewis Marshall, aged 80.

SLINGER.—On Sept. 10th, Robert Townley Slinger, F.R.C.S., of Foregate street, Worcester, aged 49 years.

WARNER.—On Sept. 8th, suddenly, after an operation, Winifred Warner, M.B., B.S., of Gold Hill House, Chalfont St. Peter.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

CONGRESS OF THE ROYAL SANITARY ASSOCIATION OF SCOTLAND.

THIS Association, which has lately held its fifty-fifth annual congress at Kirkcaldy, may be said to have done more than any single agency to raise the standard of public health administration in Scotland. It combines the professional and administrative in a specially intimate way, and the result is the cultivation of understanding between officer and authority both central and local.

This year's President is Mr. Harvey, of Edinburgh, for many years convener of the health committee. In his opening address he advocated propaganda by health authorities on the ground that removal of the poor-law stigma, along with the prolonged period of unemployment, must be counter-balanced by persuading people to look after themselves and so avoid hospital. In a popular lecture Dr. Parlane Kinloch, Chief Medical Officer of the Department of Health for Scotland, sketched the growth of health services from the days of the old "parochial boards" to the modern system of school health administration, maternity service, and child welfare, milk inspection, meat inspection, housing, tuberculosis, insurance, therapeutic substances protection, and others. All these date from 1908 and most of them are post-war. In describing the regional scheme of hospital services and general health services and the facilities for specialised advice and treatment, Dr. Kinloch commented on the absence of team-work among doctors, and stressed the importance of regional development as a means of securing immediate advance towards an efficient and economic health service.

Dr. John Guy, deputy medical officer of health and tuberculosis officer for Edinburgh, read a paper on the Economic and Nutritive Aspects of Diet. On a theoretical basis, and giving adequate amounts of all the constituents, he found that a fully balanced and varied ration could be had on 6*s.* a week, but this required some knowledge of food values. The cheapest form of diet was one consisting chiefly of oatmeal, herring, bread, margarine, and potatoes. This worked out at about 3*s.* 6*d.* to 3*s.* 9*d.* per head per week. But such a diet was monotonous and unattractive—a failing which, in his view, led to the use of condiments by the poor. The town-dweller needed a variety in his diet such as the agricultural labourer did not demand. About 18 months ago Dr. Guy studied the dietaries of some 30 families in Edinburgh, their cost ranging from 4*s.* 1*d.* to 9*s.* 9*d.*, with an average of 7*s.* He found that only 8 of the 30 gave the amount of protein usually accepted as necessary in the diet of a person at rest, and if these 30 diets were typical vast numbers of people must be living on slightly over bare subsistence diets. In the buying of food greater ignorance was shown than in the buying of any other commodity.

In an address on Town and Regional Planning Mr. George D. Macniven, F.R.I.B.A., said that building by-laws had laid a good foundation in securing a certain minimum standard of air-space, light and ventilation, and restraint of overcrowding, but that, under those very by-laws, the suburbs had grown into utter drabness and monotony. This showed that something had been lacking. Town-planning aimed at preventing disease, and therefore promoting health; at preventing ugliness and preserving beauty; at preventing congestion and confusion, and therefore safeguarding industrial and commercial efficiency. Mr. James McAllan, veterinary officer for the city of Aberdeen, pleaded for the prohibition of hawking meat from barrows and stalls on the street. He regretted the great flaw in the definite, uniform, and national system of meat inspection—namely, that the local authorities had not greater powers for the actual control of the handling and transport of meat and meat food products.

The Congress was attended by some 500 delegates. The President-elect is Dr. T. F. Dewar, of the Scottish Health Department.

PAINFUL FIBROSITIC NODULES.

To the Editor of THE LANCET.

SIR,—I suggest that "M.B., B.Ch." should try either diathermy or ionisation. Dr. Lewis Jones, in his "Medical Electricity," states that "These cases are much relieved by ionisation, and salicylic or iodine ions may be used."

I am, Sir, yours faithfully,

MAY RATHBONE.

Keston, Hayes, Kent, Sept. 14th, 1929.

THE VENTILATION OF A PICTURE THEATRE.

A REPRESENTATIVE of THE LANCET lately visited the new Commodore Super Cinema at Hammersmith which is to hold 3000 people. In such a building everyone ought to have plenty of warm, clean, dry air, and, recognising this necessity, the proprietors of the theatre have spent some £15,000 on installing a modern ventilating plant.

That there may be no shortage, air will be provided for 3500 people at the rate of 1500 cubic feet per person per hour, in six changes. Seeing that 1 cubic foot of air weighs about one-twelfth of a pound, the hourly supply for each person will be some 125 lb., or rather over a twentieth of a ton, and the total supply of the theatre about 200 tons of air per hour. The magnitude of the task of ventilation is thus evident. The air is taken from the roof of the building, 60 feet above the street level, and is drawn through a preheater, where if necessary it is warmed to prevent it from freezing the washing water, which it meets in the cleansing chamber as an impalpable mist, emitted from myriad jets. Here the gross impurities fall out, and no drops of water go further, being baffled by the eliminator plates. Through these the air, clean but saturated with moisture, passes to the secondary tempering coils and then to the fan which carries it to the roof of the theatre, where it is further warmed if required, and distributed above the heads of the visitors, to be drawn out at last under their feet. It is intended that the air supplied shall never have a wet-bulb temperature lower than 52° F., but it is important that distribution shall be made at a desired temperature. This is controlled from the ventilating engine-room where an indicator shows, by thermo-electric circuits, the temperature in any one of some dozen sections of the house. The operator can alter the temperature as he likes, having beside him another board with five lines of compressed air relay switches, each of which controls one of the five unit steam heaters which, in each of the sections, warms the incoming air.

There will be no cold draughts in this theatre when the doors are opened, for there will always be a positive pressure of warm air within it. The visitors, even if their boots and clothes are wet, will not be chilled. Their clothing will tend to dry without chilling them, and the risk of infection from person to person will be lessened by the withdrawal of expired air towards the feet. Fog is mostly removed, so the pictures will be seen the more clearly. No one will be inclined to sleep because the atmosphere is stuffy, and the audience's eyes and ears will be relatively alert. These are all benefits for the audience, while the management will gain by a reduction in the cost of cleaning the theatre and by the longer life of all furniture—owing to the lessened quantities of dust and sulphuric acid entering the house—and by the continuing patronage of people who find themselves comfortable. We are informed that a bacterial control on the ventilation would have been arranged had the designer found any literature on the subject. If such information should become available, and if it seems expedient, he hopes he may be able to add some suitable odourless antiseptic in an effective proportion to the washing water in the cleansing chamber.

We are obliged to the management of the theatre for permitting a view of the premises, and to Mr. H. A. Stirzacker, technical manager to Messrs. J. Jeffreys, the contractors for the heating and ventilation, for explaining the ventilating plans to our representative.

THE AUTUMN PHOTOGRAPHIC EXHIBITION.

THE seventy-fourth annual exhibition of the Royal Photographic Society of Great Britain, now being held at 35, Russell-square, W.C., keeps up the high standard of previous years. Medical men will find their chief interest in the scientific section, where are to be seen a series of pictures of mouse tumour cells taken with the aid of the ultra-violet miscroscope at a magnification of 1800. Here also are photomicrographs of the interior of the eye, illustrating the pathological changes resulting from lead poisoning, high blood pressure, and other conditions. A set of colour photographs of the eye by Mr. L. D. Redway merits attention. Dr. G. H. Rodman shows studies of the house fly and a graphic representation of the way in which a nettle stings, while Kodak, Ltd., are well represented with a fine set of X ray photographs, including one showing clearly renal calculi. The exhibits in the natural history room bear witness to the patience and ingenuity necessary to the achievement of success in this branch of the art. Of particular interest are flashlight photographs of a stoat, and of a honey-bee in flight, the latter showing to perfection the detail of the wing. In the library are shown the various stages in the reproduction of illustrations by the half-tone, line, photogravure, and photo-litho processes. In the pictorial section the most pleasing among many attractive prints is No. 137. No visitor should miss the lantern slides and colour plates in the studio, and a demonstration of natural colour cinematograph films. The exhibition remains open until Oct. 12th.

A Review

OF THE

NERVOUS AND MENTAL ASPECTS OF PERNICIOUS ANÆMIA.

BY DOUGLAS McALPINE, M.D. GLASG.,
M.R.C.P. LOND.,

PHYSICIAN IN CHARGE OF THE DEPARTMENT FOR NERVOUS DISEASES, MIDDLESEX HOSPITAL; ASSISTANT PHYSICIAN, HOSPITAL FOR EPILEPSY AND PARALYSIS, MAIDA VALE.

FRESH interest in the subject of pernicious anæmia in all its bearings has dated from the appearance of Hurst and Bell's [9] paper on achlorhydria in subacute combined degeneration of the cord, Price-Jones's [13 14] observations on the constancy of megalocytosis in pernicious anæmia, and more recently the excellent results of Minot and Murphy's [11] liver diet.

I have here made an attempt to review the neurological and mental aspects of the disease in a wider sense than is usual in text-books, to deal with certain points in early diagnosis, and finally to consider the results of liver therapy on the nervous complications. For this purpose 24 cases have been studied. Although relatively few in number, they serve to illustrate the points mentioned above.

In the first place, with regard to the incidence of so-called "subacute combined degeneration of the cord" I will quote only one set of figures—namely, those of Woltman [22] who in 1919 examined the nervous system in 150 cases of pernicious anæmia. In just over 80 per cent. he found "indisputable evidence of destruction of nerve parenchyma."

PATHOLOGY OF SUBACUTE COMBINED DEGENERATION OF THE CORD.

There are points regarding the nature of the changes in the cord which are still unsettled, but the following, I think, fairly represents the general consensus of opinion. Two types of lesion occur: (1) Foci in which the myelin sheaths of the nerve-fibres are destroyed, resulting in the formation of numerous vacuoles. These foci are found in the white matter, especially in the posterior columns, cerebellar tracts and pyramidal tracts, both crossed and direct. They make their appearance first in the lower cervical and upper half of the dorsal region of the cord. They are irregular in shape and tend to occur near the periphery of the cord. This distribution suggests that they bear a close relationship to the small entering arterioles. These foci of degeneration constitute the essential lesion. (2) Secondary degenerations in the long tracts of the cord; these occur only in the more chronic cases and can be recognised by their more homogeneous distribution. They result from the destruction of the axis-cylinders, a further stage of the initial lesion. Most authorities are agreed that the posterior roots are not affected. With regard to the peripheral nerves, according to Buzzard and Greenfield,[3] they are healthy. Russell, Batten, and Collier,[17] in their original paper, written in 1900, described the pathological findings in nine cases; only one of these showed definite changes in the peripheral nerves. Yet Collier [5] has recently written "some degeneration is always present in the peripheral nerves." The literature contains very few references to this point and it is obvious that this part of the nervous system has not received the proper attention of those who have studied the pathology of this disease. The cases in which a careful examination of the peripheral nerves has been made are so few that no conclusions can be drawn from them. It may be remarked, however, that definite changes have been met but they are not constant.

EARLIEST SYMPTOMS OF INVOLVEMENT OF THE CENTRAL NERVOUS SYSTEM.

Various forms of *paræsthesiæ* are common at the onset, such as a sensation of tingling, numbness, pins and needles, coldness, tightness, &c. Later in the disease a feeling as if something were tied round the leg or a sensation of walking on cotton-wool is not uncommon. In eight cases pain in the lower limbs was a prominent feature, usually in conjunction with one of the other forms of paræsthesiæ. It was generally described as sharp and stabbing, sometimes being sufficiently severe as to interfere with sleep.

With regard to the distribution of the paræsthesiæ, they were always referred to the periphery of the limbs. In a few cases one limb was affected before the others but the distribution soon became symmetrical. In approximately half the cases the paræsthesiæ were first felt in the feet, the big toe being, not uncommonly, the starting-point; in all these cases the hands were affected at a later date. In eight cases the hands and feet were affected at the same time; in five cases the hands were attacked first. In one case a "pins-and-needles" sensation was felt in the fingers of one hand for seven years before becoming generalised. The paræsthesiæ tend to spread centrally, in the case of the arms from the fingers up to the elbows and in the legs from the toes up to the knees, thighs, and in some cases to the waist. Paræsthesiæ generally precede the onset of motor disability, either in the form of paresis or ataxia, by some months, and in two cases in this series by seven and eight years respectively, although in acute cases difficulty in walking is noticed within a week or two of the onset.

Alteration in the Reflexes.

A spastic paraplegia is commonly regarded as the usual form of the disease, the deep reflexes in the lower limbs disappearing shortly before death. The following table shows the condition of the reflexes in the lower limbs in 24 cases, when first coming under observation:—

Cases.	Knee-jerks.	Ankle-jerks.	Plantar responses.	Cases.	Knee-jerks.	Ankle-jerks.	Plantar responses.
6	+ +	+ +	↑	3	+	+	↓
2	+	0	↑	3	+	0	↓
3	0	0	↑	6	0	0	↓
1	+	+	↑↓				

From this table it will be seen that there were only 11 cases (45 per cent.) in which there was unequivocal evidence of pyramidal tract involvement.

INTERPRETATION OF SYMPTOMS AND SIGNS.

In the earliest stage of the disease there may be no loss of sensation in the extremities, despite the definite subjective sensations felt by the patient. Eventually, however, two varieties of sensory loss may occur: (1) Diminution or loss of vibration sense, either alone or occasionally accompanied by impaired postural sensibility in the toes and fingers. The other forms of sensation are unaffected. This type of dissociated sensory loss is explained by the commencement of the disease in the posterior columns, usually the columns of Goll, which convey the impulses of postural sensibility and vibration sense up to the sensory nuclei in the medulla. (2) Impairment of all forms of sensation in the periphery of the limbs in the "glove-and-stocking" distribution, so characteristic of a peripheral neuritis. In this series of cases these two forms of sensory loss occurred with about equal frequency when the patients first came under observation. The second type of sensory loss can best be explained by a lesion of the peripheral nerves. Further proof of this is afforded by the occurrence of pains "cramp-like" or sharp in the limbs, accompanied sometimes by definite tenderness. Such pains certainly are due to effects of the neurotoxin on the peripheral sensory neurone. Pains in the lower limbs were a prominent feature in a third of the cases in the present series. When we come to study the reflexes, I have already shown that absent deep reflexes in the lower limbs, with or without an extensor plantar response, occurred in over half the cases. The abolition of the deep reflexes has been explained by the effect of the disease on the posterior columns. There is no anatomical proof, however, that the reflex arc passes through these columns. An easier solution to the problem would be to implicate the posterior root or posterior root entry zone. However, the consensus of opinion amongst those who have studied the pathology of the disease seems to be that these parts escape. Again, when looked at from the point of view of anatomy, the abolition of the deep reflexes on the basis of a cord lesion is equally difficult to explain. As previously stated, the cord is first affected in its middle third. Yet it is by no means uncommon to find the ankle-jerks disappearing early in the disease. This reflex is situated in the lowest part of the cord—viz., sacral segments 1 and 2. These points, therefore, suggest that the interruption of the reflex arc does not take place in the cord or posterior root, but in the peripheral nerve.

It is reasonable to deduce from this fact and the peripheral type of sensory loss that the peripheral sensory neurone is almost constantly affected, either alone for a time, or concurrently with the spinal cord.

MENTAL CHANGES IN PERNICIOUS ANÆMIA.

These are briefly dismissed in most text-book descriptions of the disease. That mental changes do occur more frequently than are supposed may be deduced from the fact that within recent years several important papers on this subject have appeared. Addison,[1] in his original description of pernicious anæmia, refers to "occasional wandering and indeed a terminal delirium." We are not here concerned with these terminal manifestations, but with those arising early in the disease. In 1905 Langdon,[10] in a paper entitled Nervous and Mental Manifestations of Pre-pernicious Anæmia, drew attention to a group of cases in which nervous and mental symptoms might precede the typical picture of pernicious anæmia. Amongst the mental symptoms he noted peevishness and a gradual mental deterioration, varied, however, by periods during which the patient more or less returned to normal. In these cases, when first seen, in addition to the mental changes, there might be symptoms and signs pointing to involvement of the spinal cord, prior to the development of the pernicious feature of the anæmia. His views were severely criticised, but with the knowledge that has accumulated since then regarding the disease it is now evident that such cases occur not uncommonly. With regard to the mental side of the question his views have recently received striking confirmation by the work of Warburg and Jorgensen,[19] which will be mentioned later. Their paper, incidentally, contains an excellent bibliography relating to the mental changes in pernicious anæmia. Only one or two of the more important papers on the subject will be mentioned. Pickett,[13] in six cases of pernicious anæmia, noted shallow confusion with impairment of ideas of time and space. Delusions, especially of a persecutory character, he believed to be common. Barrett,[2] in an important paper, studied the mental changes in 11 cases. In nine of these he made a histological examination of the brain. The commonest symptoms were delusions of persecution, sometimes systematised, disorientation in time and space, confabulation, irritability, but little mental deterioration. The blood picture in nearly all the cases was that of a severe pernicious anæmia. In over half the cases there was a psychopathic family history. Histologically all the cases showed varying degrees of destruction of the long tracts in the cord. The changes in the brain were not uniform but the commonest findings were: (1) rarefaction of perivascular nerve-fibres, (2) endarteritis, (3) changes in the nerve-cells, (4) in several cases areas of focal disintegration of the myelin sheaths.

Woltmann[21] described the histological changes in the brain in seven cases. Amongst his conclusions are the following: (1) Not only do degenerated areas, such as are typically found in the posterior and lateral columns of the spinal cord in pernicious anæmia, occur in the medullary portion of the brain, but they do so with about the same frequency, though their demonstration may be rendered more difficult. (2) In addition, there is sometimes a diffuse degeneration, which though it is, as a rule, somewhat more marked in the long association traces, also occurs in the short commissural fibres passing from one gyrus to another. (3) The grey matter is by no means immune from the destructive process, which usually occurs focally around the pyramidal cells, some of which may be destroyed. (4) Well-marked psychoses, such as are occasionally associated with pernicious anæmia, probably have little or nothing to do with these destroyed areas, but the milder mental manifestations, such as somnolence and apathy, may be dependent on them.

In the present series the mental condition of the patient was investigated in 17 cases. In 11 of these some departure from the patient's normal mentality was noted. In three cases this merely amounted to depression with lack of mental energy.

Depression with Lack of Mental Energy.

In none of these cases was the blood count below 3,500,000 red cells, so that anæmia, per se, could not be held responsible for the condition. In one of the cases marked improvement in the patient's mental outlook followed liver treatment. In one other the depression remained; in this case the patient had been on liver treatment for one year before coming under my observation and there had been no improvement in his neurological condition. The remaining case was as follows:—

Male, aged 50, was referred to me from the Western Ophthalmic Hospital on account of recent retinal hæmorrhages. Nothing of note was found in his cardiovascular system, and the urine was free from albumin. Further questioning of the patient elicited the fact, which he had not previously mentioned, that for the past three months he had noticed a numb feeling in his legs, and that his feet always felt cold. He showed a slight impairment to all forms of sensation below the knees, with loss of vibration sense below the level of the anterior superior iliac spine. The knee-jerks were present, but the ankle-jerks could not be obtained. The right plantar response was equivocal; the left flexor. The average blood count before treatment was as follows: R.B.C., 3,500,000; Hb., 77 per cent.; C.I., 1·05.

A fractional test-meal showed complete achylia. He was in hospital from December, 1927, for three months. His mental condition throughout was one of mild depression and indifference. He had never previously felt depressed. His blood picture slowly improved under liver treatment, but there was no corresponding improvement in his neurological condition. He committed suicide three months after leaving hospital.

Confusion with Failure of Memory.

Four cases showed a mild state of confusion, which varied in intensity in the same patient from time to time. Failure of memory, for both recent and past events, indifference and even apathy, slow cerebration, and a tendency to somnolence were the prominent features in these cases. The following is an example of this group.

Male, aged 61, was seen by me early in 1928. According to his son, following an "influenzal cold" in 1924, a marked change in his mentality was noticed. He had always been regarded as a man of intellectual type, but he then began to lose interest in his work and made elementary mistakes. He became childish in his general outlook on life, and often "seemed to be in a dream." This mental deterioration was gradual. In 1926 he developed numbness in his fingers and toes, which persisted. When examined in June, 1928, he appeared mentally dull and indifferent. His memory was markedly defective for both recent and past events. There were no hallucinations or delusions or disorientation in time or space. There was no definite paresis of the lower limbs. The knee-jerks were sluggish on admission to hospital, and soon disappeared. The ankle-jerks were absent. The plantar responses were equivocal. There was hypoæsthesia to all forms of sensation below the knees. Vibration sense was diminished up to the level of the seventh rib. There was slight loss of postural sensibility. A blood count showed R.B.C., 3,570,000; Hb., 67 per cent.; C.I., 0·93. There was complete achylia. The Wassermann reaction was negative in the blood and cerebro-spinal fluid. As a result of three months liver treatment he lost 18 lb. in weight. His blood picture, however, showed slight improvement. On discharge there was little or no alteration in his neurological or mental condition. Since then he has continued liver treatment as well as hydrochloric acid. When seen on July 20th, 1929, his condition was about the same.

Toxic Psychosis.

In the following three cases a definite toxic psychosis, with symptoms of a paranoidal nature, was present.

Female, aged 57, was admitted under my care in March, 1929. She had enjoyed good health until the summer of 1927, when she began to experience numbness in the big toe of either foot, and at times sharp pains in her legs. Later a frozen feeling, with numbness, was felt in the hands. These symptoms became aggravated, and later difficulty in walking was experienced. She was inclined to be sleepy, depressed, and irritable. She thought that no one wanted her, that everyone was looking at her, and that her neighbours had taken a dislike to her. On admission she appeared depressed, but otherwise normal mentally. There was no history of depression in the past. There was slight paresis of both lower limbs, with loss of deep reflexes. Both plantar responses were flexor. There was "glove" anæsthesia in her hand and marked loss of all forms of sensation below the knees. A blood count showed: R.B.C., 2,950,000; Hb., 70 per cent.; C.I., 1·8. There was complete achylia. She was treated with half a pound of liver daily, and dilute hydrochloric acid. The mental symptoms quickly disappeared. The blood picture gradually improved. On discharge from hospital on March 22nd: R.B.C., 4,033,000; C.I., 0·06. The paræsthesiæ had become much less pronounced, and she was able to walk with the support of a stick. In June, 1929, she reported herself as still further improved.

Male, aged 46, was admitted into Maida Vale Hospital, under the care of my colleague, Dr. A. Felling, in April, 1924. In October, 1922, he first complained of pain and numbness in the ankles, which gradually spread up to the thighs. In September, 1923, he was admitted to the National Hospital, Queen-square, where a diagnosis of subacute combined degeneration of the cord was made. After about a month in hospital he became mentally confused and suicidal. He was discharged to an infirmary, but made a good recovery within a few weeks. In March, 1924, the left leg became weak, and he was unable to walk. On examination in April, 1924, he appeared pale and depressed. There was a typical glossitis. The legs were spastic, with double extensor plantar responses. There was hypoæsthesia to cotton-wool and pin prick below the knees. Vibration sense and postural sensibility were much impaired. A blood count showed: R.B.C., 3,200,000; Hb., 65 per cent.; C.I. 1·0. There was complete achylia. At the beginning of June, 1924, he developed persecutory ideas; he thought that his food was being poisoned, and that everyone was against him. He discharged himself from hospital, and died in July, 1925.

The following case is of especial interest. Female, aged 41, early in 1925 first experienced a tingling sensation in the ring and little fingers of the left hand, followed later by a pins-and-needles sensation in the same fingers, an aching and cold feeling around the ankles, and dull aching pains in the feet and legs. In March she noticed that her walking was affected. In May she was admitted to the West Middlesex Hospital on account of the pains in the legs and vomiting. After three days there she became excitable and at times violent. She took off all her clothes, refused to eat, thought she had been cut up, and threatened to commit suicide because she was being ill-treated. She was transferred to Springfield Mental Hospital on May 20th.

I am indebted to Dr. R. Worth for permission to use the notes, of which the following is an extract:—

Past and Family History.—She had never before suffered from any form of nervous breakdown. One sister had been insane for a week at the climacteric. Otherwise there was no psychopathic history in the family.

On admission she showed some clouding of consciousness. She was not disorientated, but her memory for recent events was very poor, for current and remote events fair. She was suffering from delusions—e.g., stated that she had been through an operation that morning. She was somewhat restless. She complained of abdominal pain, and there was a very offensive diarrhœa. No definite neurological signs were noted. There was slight motor weakness in the lower limbs. The deep reflexes were active, and the plantar responses flexor in type.

June 2nd, 1925.—Mental condition about the same, but depression more marked than on admission. Abdominal pain still complained of, and diarrhœa continues. 3rd: Quiet; rather confused. Memory for current events, poor. Signs of colitis abating. 10th: Improvement in mental condition. She answers questions sensibly and is beginning to take an interest in her surroundings. Diarrhœa has now stopped, and she appears stronger. 17th: Much better mentally and physically. The only mental abnormality now present is a tendency to worry over trifles. July 24th: Improvement in mental condition has been maintained. August 8th: Discharged as recovered.

She was admitted to the Hospital for Epilepsy and Paralysis, Maida Vale, six weeks later—Sept. 22nd—under the care of Dr. C. M. Wilson, complaining of weakness and numbness of the legs, unsteadiness in walking, and a feeling as if she was walking on cushions. Her arms felt stiff and numb up to the elbows. Mentally she appeared somewhat emotional and her attention was poor. The tongue was red and glazed. There was slight paresis in the legs. The knee-jerks were active; the ankle-jerks were absent. The plantar responses were flexor. A blood count showed R.B.C., 3,288,000; Hb., 57 per cent.; C.I., 1·0. Wassermann negative in blood and cerebro-spinal fluid. There was complete achylia. She left hospital in December, 1925, improved. Unfortunately this patient cannot now be traced.

The chief interest in this case lies in the association between the psychotic state and the attack of diarrhœa, which was almost certainly a symptom of pernicious anæmia.

THE RELATION BETWEEN MENTAL SYMPTOMS AND PERNICIOUS ANÆMIA.

Warburg and Jorgensen,[19] in a recent paper which should be read in the original, draw attention to the occasional association of psychoses and neurasthenia, with achylia gastrica and megalocytosis and discuss the relationship between this syndrome and pernicious anæmia. In their conclusions they state that there is a chronic pathological condition, associated with achylia gastrica, which covers a great many cases of neurasthenia and some cases of early psychoses, and that these mental disorders are often associated with mild spinal symptoms, glossitis, and megalocytosis. The epoch of pernicious anæmia is a rare and late stage in this condition, in which, not infrequently, one observes anæmia with a low colour-index at an early juncture. The majority of their cases improved with liver treatment. Their findings fit in well with Langdon's original conception of a pre-pernicious anæmia, in which mental or neurological symptoms may first dominate the clinical picture. With regard to the incidence of achylia in the psychoses, Ford-Robertson[8] has recently investigated this matter as part of an inquiry into the relationship between gastro-intestinal infection and mental disorder. He comes to the conclusion that gastric dysfunction, especially hypochlorhydria, is present to a much greater extent than in normal persons. In 14 cases (12 per cent.) he found absence of free hydrochloric acid after a test-meal; whilst 35 cases showed a diminished amount of free hydrochloric acid.

Reviewing the cases in the literature and those referred to in this paper, it seems certain that mental changes of varying severity occur not uncommonly in pernicious anæmia, sometimes in its earliest or pre-pernicious stage. The condition may range from a state of depression and lack of mental energy to a mild and even severe confusional psychosis. Frequently paræsthesiæ in the limbs may accompany or follow the mental symptoms, indicating the generalised effect of the neurotoxin on the central nervous system.

The early recognition of these symptoms, by means of an examination of the blood and gastric contents and their adequate treatment, may result in considerable improvement.

Diagnosis of Pernicious Anæmia.

What are the necessary criteria for the diagnosis of this disease? First and foremost comes *achylia*, which was present in each of the 21 cases in which a gastric analysis was made. A fractional test-meal is unnecessary. A stomach-tube should be passed before the test-meal is given in the morning, and the presence or absence of free hydrochloric acid determined in the resting gastric juice. Specimens taken one and two hours after the test-meal should be similarly tested. This can be done qualitatively by means of a drop or two of methyl-orange, which is added to the specimen. If free hydrochloric acid is present an orange colour develops. This test can be carried out by the general practitioner without any special apparatus and without taking up too much of his time.

Secondly comes the *examination of the blood.* This may show a definite picture of pernicious anæmia—e.g., low cell count with high colour-index and megalocytosis. Not infrequently, however, the red cells are but little reduced in number or may even exceed five millions; in such cases the colour-index may be low—e.g., 0·7 or 0·8. In the present series several cases which were under observation in hospital, and on whom blood counts were performed on an average three times a week before and after treatment with liver, showed a colour-index not exceeding 0·9. Campbell and Conybeare,[4] in a large series of cases of pernicious anæmia, found the colour-index to be above unity in only 60 per cent. of their cases. I think this point ought to be emphasised, as the majority of text-books lay undue stress on a high colour-index as an important feature in the diagnosis of pernicious anæmia. There is one feature of the blood picture which is constant before and probably after liver treatment—namely, an increased diameter of the red cells or megalocytosis. Price-Jones [15] [16] originally described this condition and a method by means of which the average diameter of the red cells is arrived at. As a dried film is used, the method cannot be really accurate owing to alterations in the size of the cells. Its chief drawback, however, lies in the time required to do a count—namely, about two hours.

Pijper,[14] in 1924, devised an indirect means of measuring the *diameter of cells.* By means of a strong beam of light, which is allowed to pass through a lens of a known focal length and through a dried blood film, coloured rings are produced by diffraction, from which it is possible to calculate the diameter of the cells by measurement. I have tried this method, but was unable to obtain constant results.

Recently Eve[7] has described an instrument which he calls the Halometer. This is intended as a rough guide to the size of the red cells for the use of practitioners. It depends on the same theory as that underlying Pijper's instrument—namely, a thin blood smear acts as a diffraction grating and splits up the rays from a small source of light into a brightly coloured halo. I have used this instrument in a number of cases. I found that dried slides, two or three weeks old, gave too low readings. The blood film must be fresh. In three out of four cases, in all of whom the blood count exceeded 4½ million red cells, and who had been under treatment with liver for several months, the readings on the scale were just within the " pernicious anæmia zone." In one of the cases there was a low normal reading. This instrument certainly should provide the general practitioner with a means of substantiating a suspicion of pernicious anæmia, which could be further reinforced by gastric analysis and examination of the blood. An accurate method of estimating the size of the red cells, and at the same time a method which does not require any length of time, is still required. Lastly, the presence of a *Hunterian glossitis*, although not a constant feature of pernicious anæmia, frequently provides a valuable diagnostic link.

EFFECTS OF TREATMENT ON NERVOUS COMPLICATIONS.

With the advent of liver treatment, and its remarkable effects on the blood picture, it was thought by some and hoped by many that a panacea for all the evils of pernicious anæmia had arrived. As far as the spinal cord symptoms are concerned this has not proved to be the case, except in the opinion of a few. Minot and Murphy[12] treated 31 cases of pernicious anæmia, which showed definite evidence of involvement of the central nervous system. They found that the paræsthesiæ and ataxia were improved, but that the reflexes remained unaltered. Recently developed symptoms of injury to the nervous system usually yielded more rapidly and satisfactorily than those due to old-standing lesions. They further state that no improvement usually takes place until the red cell count has reached four million. Symptoms have not definitely progressed or developed under adequate dietary treatment. Davidson, McCrie, and Gulland[6] found that in the tabetic type of subacute combined degeneration of the cord very marked improvement may occur, but in cases of the spastic type there was no improvement. A few other isolated cases have been reported, in some of which improvement has been noted; in others none. Much the largest series of cases are those described by Ungley and Suzman.[18] They report their observations in 61 cases of subacute combined degeneration of the cord, observed at the Royal Victoria Infirmary, Newcastle, since 1925. The large number of cases is striking, and suggests that pernicious anæmia is a commoner disease in that part of England than in London. Thirty of these cases were treated by liver therapy. Of the 31 cases that had no liver, 28 died within an average period of 4·6 months from the onset of the disease. Of those treated with liver, 17 were improved, eight remained stationary or became worse, and five died. The authors state that the results have been very promising. Numbness and tingling, as a rule, disappear entirely, postural sensibility is re-established more or less completely, and, as a result, incoördination and ataxia diminish or disappear. Further, vibration sense often returns, although in some cases it has remained absent. In three cases the plantar responses became changed from the extensor to the flexor type. Sphincter troubles also were improved. They conclude " that since all evidences of cord involvement may disappear, it is clear that the degenerative changes in the white matter in this disease are not of a permanent character." I have analysed their case reports, especially from the point of view of the degree of anæmia present. In 13 cases they give details of blood counts before and after liver treatment. The average number of red cells in these cases before treatment was 2,300,000. The approximate average after treatment was 5 million. In some of the 12 cases that did not improve on liver there is insufficient data, with regard to the blood counts, from which to draw conclusions. It is obvious, therefore, that the degree of anæmia should be taken into account when considering the possible action of liver treatment on the neurological symptoms as distinct from its effect upon the blood picture.

In my own series of cases the results were not nearly so favourable. Eleven cases have been treated with liver, and adequate doses of dilute hydrochloric acid have been given over periods exceeding six months. Four cases have made slight improvement, three are stationary, and four are worse. None of the four cases that have improved showed definite evidence of pyramidal tract involvement, and their deep reflexes were absent. All four cases in which the condition slowly progressed were of the spastic type. As several of the cases that were not treated by liver could not be traced after leaving the hospital, no comparison is possible between these and the liver-treated cases, but my impression is that life is prolonged in the latter group.

The general effects of liver treatment which have been observed are as follows: 1. An improvement in the blood picture, which, however, in some of the cases has been slow, even though 1 lb. of liver, or its equivalent, in the form of an extract, has been given daily. 2. The general condition has improved, especially with regard to appetite and digestion. Glossitis, if present, has lessened. 3. Paræsthesiæ become less marked, but their total disappearance, even after months of regular liver treatment, has been rare. 4. No appreciable alteration in the reflexes has been noted, although in one case an extensor response became equivocal. 5. Ataxia has in some cases improved; all of these cases had walking exercises. 6. Mild mental symptoms usually disappear.

The spastic type of subacute combined degeneration of the cord, in whom the degree of anæmia is slight, as a rule slowly progresses despite treatment. Ungley and Suzman's conclusions are, I feel sure, too optimistic. The type of case which shows the best results is that in which the reflexes are diminished or lost and there is no pyramidal tract involvement. Two well-established points in treatment must not be overlooked: (1) eradication of all sepsis, especially dental; (2) the administration of dilute hydrochloric acid in ʒi doses thrice daily. Although liver treatment offers an efficient protection to the blood, it does not act in the same way against the effects of the intestinal toxin on the nervous system. The best method of combating the neurotoxin is to raise the patient's resistance to infection as far as possible by the removal of sources of sepsis, prevention of anæmia by means of liver, and elimination of the toxin originating in the upper intestinal tract by the administration of adequate doses of dilute hydrochloric acid.

CONCLUSIONS.

1. The neurotoxin, associated with pernicious anæmia, may attack all parts of the nervous system, cerebrum, spinal cord, and peripheral nerves, although not necessarily simultaneously.

2. In subacute combined degeneration of the cord the peripheral nerves are generally affected, especially in the so-called "tabetic type" of the disease.

3. Pernicious anæmia is a common cause of peripheral neuritis in persons over the age of 35. If the tongue be affected, the diagnosis becomes more probable.

4. Mental changes occur not uncommonly in pernicious anæmia. They range from states of depression, accompanied by loss of mental energy, to definite psychoses. They, like the nervous symptoms, may precede the characteristic changes in the blood by many months. More frequent examination of the gastric contents and of the blood, especially for the presence of megalocytosis, is called for in primary neuroses, and psychoses occurring after the age of 35, in view of the favourable results that may follow adequate treatment, instituted at an early stage.

5. The effects of liver treatment on the neurological symptoms are variable. In cases showing a marked degree of anæmia the improvement may be largely attributed to the favourable effect of such treatment on the blood and general condition. When an extensor response exists this improvement is slight; the progress of the disease may for a time be arrested, but not uncommonly it advances despite adequate treatment.

6. The type of case with abolition of deep reflexes, in which it is suggested that the peripheral sensory neurone largely bears the brunt of the disease, at least in the early stages, is naturally the most favourable.

7. The well-established rules regarding the eradication of dental sepsis and the administration of hydrochloric acid still maintain their importance.

I am much indebted to several of my colleagues at the Hospital for Epilepsy and Paralysis for permission to examine certain of the cases which were under their care.

OBSERVATIONS ON
HARMINE IN THE TREATMENT OF CHRONIC EPIDEMIC ENCEPHALITIS.

BY T. R. HILL, M.B., M.R.C.P. LOND.,
ASSISTANT MEDICAL OFFICER-IN-CHARGE OF POST-ENCEPHALITIS UNIT, METROPOLITAN ASYLUMS BOARD;
AND
C. WORSTER-DROUGHT, M.D. CAMB., M.R.C.P. LOND.,
PHYSICIAN TO THE WEST END HOSPITAL FOR DISEASES OF THE NERVOUS SYSTEM AND CONSULTING PHYSICIAN, POST-ENCEPHALITIS UNIT, METROPOLITAN ASYLUMS BOARD.

IN 1928 Lewin reported the results of his experiments on the pharmacological effects of the plant *Banisteria caapi* and of an alkaloid extracted from it which was termed "banisterine." He found that in laboratory animals and in man banisterine produced stimulation of the central nervous system, followed, especially with larger doses, by depression. As a result of this work the alkaloid was tried in cases of post-encephalitic parkinsonian rigidity and was said to have produced benefit equal or superior to that obtained by administering hyoscine. Beringer (1928) reported excellent results as regards improvement in the rigidity, involuntary movements, and muscular weakness of parkinsonism. He regarded the drug as "a new alkaloid influencing the extrapyramidal nervous system."

Identity of Banisterine and Harmine.

Following Lewin's investigations, Merck stated that banisterine was physically and chemically identical with the better-known alkaloid harmine which is obtained from the plant *Peganum harmala*. Both possessed the formula $C_{13}H_{12}N_{2}O$. Lewin was not convinced of the identity of the two alkaloids, but the claim was supported by the fact that *Banisteria caapi* was used in the preparation of *jagé*, an intoxicating drink manufactured by the Indians of Central and South America. Jagé had frequently been examined and the most recent results had left no doubt that the alkaloid it contained was harmine. Bayon isolated an alkaloid from jagé which he named "telepathine," but which was probably harmine. In addition it is significant that harmala seeds are used in the preparation of an intoxicant by natives of North Africa. The identity of banisterine and harmine appears to have been established conclusively by the recent work of Gunn, in which he shows that the drugs produce similar pharmacological effects in laboratory animals.

The reputed benefit resulting from banisterine in parkinsonism and the suggestion that it was identical with the more easily procurable harmine led to the administration of the latter drug in cases of chronic encephalitis.

Pharmacology of Harmine.

Gunn states that Tappeiner in 1895 was the first to investigate the action of these alkaloids when he gave a general account of the action of harmaline. He described (1) motor stimulation of the central nervous system, with tremors and convulsions, followed or accompanied by paresis; and (2) slowing of the pulse-rate. His experiments with harmine gave similar results. Gunn in 1910–11 came to the conclusion that the actions of harmaline and harmine greatly resembled those of quinine, but that with regard to stimulation of the central nervous system their actions resembled those of some of the other cinchona alkaloids rather than quinine itself. His further work supports these conclusions, and he mentions that Flury obtained very similar results as far as the nervous system and circulation were concerned. Many of the actions of harmine are not relevant to any effect that it may exert in parkinsonism and can be briefly dismissed. It is said to cause relaxation of the intestine and spleen, and to be powerfully toxic to protozoa. It has been used with some apparent benefit in malaria. It produces contraction of the isolated parous uterus of the rabbit and progressive shortening accompanied by gradual lessening of response to stimulation of voluntary muscle (frog's gastrocnemius); the action on all forms of muscle appears to be peripheral.

As regards the central nervous system Gunn states that harmaline does produce slight and transient increase in the excitability of the "spinal reflex" of the frog, and he considers that harmine has a similar action. The main effect, however, is "a paralysis of the spinal reflexes." Gunn found that the chief symptoms produced by harmine in the rabbit were: (1) tremor and swaying of body; (2) impulse to continual movement, especially to "running" movements or "drum-beating" movements of the fore-limbs, followed by general paresis. The tremor was aggravated by voluntary movement. From the use of harmaline in cats Gunn deduced the occurrence of hallucinations, and states that Lewin observed the same result with banisterine in dogs. Of harmine the former observer expresses the opinion that "it is possible that in larger doses it will produce a kind of intoxication in man, seeing that it has been found to produce a pronounced stimulation of the cerebrum in the lower animals."

Harmine in Parkinsonism.

Stern stated in 1928 that he had obtained a few successes in the treatment of parkinsonism with the use of harmine, and the same year Rustige published the results of his experiments with the drug. The latter will be considered in some detail.

Rustige began by giving harmine in doses of 0·005–0·05 g. hypodermically, and later increased these doses in some of the cases; 18 patients received 27 injections in all. In addition, in two cases 0·01 g. was given by the mouth three times a day for several days. All the patients before the experiment showed marked bradykinesia with muscular rigidity.

No effect was noticed on the blood pressure or pulse-rate. In every case, 7 to 15 minutes after the injection of 0·02–0·05 g. harmine, 11 patients complained of giddiness, tinnitus, and a feeling of drunkenness, and, in addition, in one case, of faintness and nausea. The susceptibility of the patients to such symptoms varied greatly. In some the effects increased in severity and duration with an increase of dose. In practically all cases these symptoms disappeared in from 15 to 60 minutes. In one case of post-encephalitic tachypnœa (with a respiratory rate of 80 inspirations per minute), without other signs and symptoms, a diminution in rate to 20–40 per minute occurred 20 minutes after injection and lasted for hours, the breathing being deep and quiet.

A clear objective diminution of muscular rigidity was found in six patients, resulting from the injection of 0·02–0·03 g. harmine. In three of these cases the very pronounced rigidity disappeared entirely, but returned after an interval of 20 minutes. In all six cases it remained somewhat reduced for six hours.

In nine patients an effect was produced on the tremor, but it was variable in nature, and in some cases, if not in all the cases, it was probably the result of suggestion.

The most pronounced effect of the drug, both objectively and subjectively, was upon voluntary movement. In 13 patients (to whom, in all, 16 injections ranging from 0·01 g. to 0·05 g. were administered) a definite improvement in voluntary movement was seen, not only in speed but in vigour, range of movement, and in the ease of performance of rapid alternating movements. This effect was noticed 10 to 22 minutes after injection and had ceased objectively after one hour at the most. Also, the general bradykinesia appeared ameliorated and the patients quicker and freer. The mental state of the patients brightened, and their subjective improvement continued long after all apparent effect of the drug had passed away.

In two cases no effect was produced upon an oculogyric crisis. Harmine given by the mouth exerted no action. No enhancing of the effects of harmine mentioned above was produced by an increase of dose except that the toxic effects of vertigo, &c., were increased in severity and duration. No dose higher than 0·05 g. was given, and the majority received doses varying from 0·02 to 0·03 g.

Only four patients denied receiving benefit, and the author believed that he had avoided the effect of suggestion in other cases.

Personal Cases Treated with Harmine.

We have administered harmine to 38 cases of generalised parkinsonism following encephalitis lethargica. This group was composed of 16 severe, 13 moderately severe, and 9 mild cases. Twenty-two patients were males and 16 females, their ages ranging from 12 to 44 years, with an average of about 26 years. In 10 cases the drug was given by mouth and in 19 hypodermically, the two forms of administration being distributed evenly over the three types of case. The following tables represent the doses and the periods for which they were given in all but two or three cases:—

By Mouth.

0·01 g. twice a day for seven days
0·02 ,, ,, ,, five ,,
0·03 ,, ,, ,, three ,,

Hypodermically.

0·02 g. every morning for seven days.
0·02 ,, three times a day for seven days.
0·04 ,, ,, ,, one day.

All cases prior to the administration had been under treatment with hyoscine given hypodermically. This treatment was stopped in all cases one week before beginning the course of harmine. During this week the condition of all the patients deteriorated greatly so that all except the mildest became very helpless, their ability to walk, talk, dress, and feed themselves being greatly impaired and in many cases completely abolished. Tremor, sialorrhœa, muscular rigidity, bradykinesia, bradyphrenia, and oculo-gyric crises were all much more evident. A few days after the completion of the harmine course, the hyoscine treatment was resumed and all the patients rapidly returned to the state in which they were prior to the omission of hyoscine.

The patients whilst receiving harmine showed no change whatever in their symptoms of parkinsonism at any time during the course. There was no amelioration of the syndrome even for a short period after each dose. Effects on the blood pressure, pulse-rate, muscular rigidity, bradykinesia, and bradyphrenia were particularly sought and none were found. Tremor, involuntary movements, and oculo-gyric crises were unaffected. The only signs or symptoms, subjective or objective, produced by the drug developed in seven patients 30 to 90 minutes after each administration of the highest of the hypodermic doses given—i.e., 0·04 g. In these cases there was a sudden onset of dizziness, generalised headache, usually nausea, and sometimes vomiting. The symptoms lasted about 30 minutes, though the headache occasionally persisted for some hours, and recurred after each dose.

After completion of the course of harmine and resumption of hyoscine hydrobromide gr. 1/100th hypodermically three times daily, nine cases were given, in addition, 0·02 g. of harmine hypodermically three times a day for 14 days with no increased benefit. Two or three cases were kept a little longer than the others on 0·02–0·04 g. harmine hypodermically, three times daily, before the resumption of the hyoscine, but no result other than the toxic effects referred to above was observed.

One case of post-encephalitic respiratory dysrhythmia, in a boy of 13 years free from parkinsonism, was treated with harmine. He was undersized and was suspected of being a mild example of the Lorain type of dyspituitarism, secondary to pituitary or hypothalamic involvement. His respiratory dysrhythmia was of the well-known type in which a deep inspiration is taken and the breath held for 10 to 20 seconds, being then expelled noisily and followed for a variable period by loud tachypnœa before the cycle begins again. In this case the administration of 0·02 g. harmine, three times a day hypodermically, appeared to produce from the start a diminution both in severity and duration of the attacks of apnœa and tachypnœa. Secondarily to this the patient slept better at night. This effect was maintained over a month of treatment with harmine.

Commentary.

The results of our experiments show that harmine administered in the doses given above exerts no perceptible effects, objectively or subjectively, other than the production of vertigo, nausea, and vomiting following the highest doses given hypodermically. These results differ greatly from the findings of Rustige and a few criticisms of his work are indicated.

Rustige's 18 patients received only 27 injections of harmine in all; consequently his conclusions as to the effects were drawn from the results of only one or two injections in each patient. That some of the apparent effects were "functional" and due to suggestion is admitted by the author, and the impression that most of them were probably so produced is gained from a close scrutiny of his paper. The likelihood of their being due mainly to suggestion is increased by the drawing of conclusions from the apparent effects of only one or two doses in each patient. It is remarkable that the reported improvement of parkinsonism was not increased by giving a larger dose of harmine and that the only enhanced effect was an increase in vertigo and nausea. If the amelioration of parkinsonism were a physical effect of harmine it would be expected to have been made more pronounced by increasing the dose. Rustige's findings differ considerably from those of Beringer, although it is now shown that they were using the same drug. Beringer reported no amelioration of the general bradykinesia and no psychical effect from the administration of banisterine. Lastly, it may be pointed out, though tentatively, for Gunn has observed that the actions of harmine vary in different animals, that the reported effects on parkinsonism are somewhat inconsistent with the effects upon laboratory animals. Rustige reports no production of involuntary movements, restlessness, or muscular contraction as immediate effects of the administration of harmine, but describes diminution of rigidity and increased freedom of movement as the first effects evident upon the musculature.

Conclusions.

1. The identity of the alkaloids banisterine and harmine appears conclusive.

2. Harmine in doses up to 0·04 g. given hypodermically has no perceptible objective or subjective effect in ameliorating any of the symptoms presented in the parkinsonian syndrome and is of no value in the treatment of this condition.

3. When given in the above doses harmine produces toxic symptoms of dizziness, headache, nausea, and vomiting in a certain proportion of cases.

4. These toxic symptoms are probably due to the action of harmine on the brain-stem—e.g., stimulation of the vestibular nuclei and vomiting centre.

5. In one reported case, and in one of our cases, the symptoms of severe chronic tachypnœa in a patient free from parkinsonism were partially relieved.

ACTINOTHERAPY.

SOME CLINICAL RESULTS OF TREATMENT.

BY ALBERT EIDINOW, M.B., B.S. LOND.

THE clinical results here described have been based upon records from over 800 cases under my personal care. Some had failed to progress by other methods of treatment, and all were selected, after careful clinical examination, as being likely to respond favourably to light. About 6000 applications of light have been given. Two methods of treatment were adopted: (1) the irradiation of the normal skin of the body—general treatment; (2) application of rays to the site of local lesions—local treatment.

The technique of general treatment has been based upon the principles of "short-ray therapy," which has already been fully described,[1 2 3] and can be summarised as: (1) exposure of an area of skin roughly equal to one-sixth of the surface area of the body; (2) an interval of 10–14 days between irradiations of any given area of skin; (3) irradiation conducted two to three times a week; (4) the application of the minimal erythema dose.

The table classifies the lamps which have been employed and the average dose of rays applied.

In the early cases the sensitiveness of the skin to ultra-violet rays was estimated by means of the "test dose armlet"; the result determined the minimal erythema dose for the type of lamp used for irradiation. In practice it was found that constant and biological dosage could be obtained by careful control of the ampèrage and voltage passing between the electrodes of a lamp. The sensitiveness of the white skin to short ultra-violet rays differs from its sensitiveness to long ultra-violet and visible rays. Thus many cases of pathological photo-sensitisation show marked hypersusceptibility to exposure to visible rays, but normal reaction to short ultra-violet rays. Children are more resistant to light than adults. The types of skin which are very sensitive to ultra-violet rays are: (1) The "rheumatic or gouty" type, having a dry skin, sweating with difficulty, and a high nitrogen content of blood or urine. The extreme types are seen in some cases of uræmia and nephritis, which are very sensitive to light. In these types erythema is very irritable, painful, and often produces a papular or vesicular rash over the whole body. Improvement is obtained by a course of "sweat-producing baths" and alkaline medicines. (2) The skin over varicose veins of the legs. (3) The type showing vasomotor circulatory disturbances, such as chilblains. This is usually associated with a white, poorly pigmenting skin, sweating, and diminished capillary tone. Marked improvement is seen in these cases after preliminary irradiation.

Table showing Classification of Lamps.

Type of lamp.	Voltage between electrodes.		Ampèrage.		Kilo-watt energy.	Time in minutes for minimal erythema for normal white skin.
	Min.	Max.	Min.	Max.		
Long-flame arc. Iron-cored carbons. 240 D.C.	55	85	25	32	1·375–2·720	3½–5
M.V.L. (atmospheric) 480 volts D.C.	200	250	2·5	5	0·5–1·25	1½–3½
M.V.L. (vacuum) 240 D.C.	105	135	2·0	5	0·21–0·675	2–5
Kromayer type water-cooled M.V.L.	105	180	2·0	7	0·21–1·26	½–2
Throat lamp.	60	120	0·6	2·0	0·036–0·240	2–4
Quartz mercury H.F.E.	—	—	300 ma.	500 ma.	—	3–5

D.C. = Direct current. M.V.L. = Mercury-vapour lamp.
H.F.E. = High-frequency electrodes. ma. = milliamèpres.

Hæmobactericidal Power.

The erythema reaction obtained by exposure of the normal skin to rays shorter than 3000 A.U. was correlated in 182 cases with an increase in the bactericidal power of the blood tested in vitro by the "slide cell technique," described by Wright, Colebrook, and Storer.[4] In each case the minimal erythema dose of rays was applied to an area measuring, roughly, 144 sq. in. Samples of defibrinated blood were collected before and two hours after irradiation. The hæmobactericidal power of each sample was determined. The following results were obtained:—

	Per cent.
Cases in which hæmobactericidal power increased after irradiation of skin	153 = 84·5
Cases in which hæmobactericidal power decreased after irradiation of skin	15 = 8·5
Cases in which hæmobactericidal power did not change after irradiation of skin	13 = 7·0

Prof. Greenwood has kindly investigated the results of these observations, and has determined the mean average bactericidal power of the cases treated before and after exposure to light. These results show that 84·5 per cent. of cases tested have increased bactericidal properties of the blood two hours after irradiation, and that the average increase is 6·5 per cent.

Experiments have been carried out[5] which suggest that a local bactericidal effect is produced at the site of irradiation, and carried later by the blood stream into the general circulation. In many cases the bactericidal property of human blood is high, and the increased bactericidal effect after radiation appears comparatively small. The fact that it is improved after irradiation can be accepted as an index of beneficial action. In some cases in which the bactericidal power was abnormally low a marked increase resulted after irradiation. Excessive dosage and over-exposure to light cause a fall in bactericidal power, and harmful results follow, as in chronic pulmonary tuberculosis. Although in laboratory experiments the hæmobactericidal power of animals has been increased by other physical agents, such as heat and mustard plasters, the application of these agents to the human skin is impossible, as the intensity of the burning or blistering necessary is too severe. While the bactericidal test of the blood is an index of the response of the human body to the erythema-producing rays shorter than 3000 A.U., it is no index of the effects of the infra-red, visible, and long ultra-violet rays. When the leucocytic function of the blood is impaired and hæmobactericidal power is low, as in some types of chronic tuberculous disease of the lungs and acute pyrexial microbic infection, dosage and treatment by short ultra-violet rays should be controlled by the study of the bactericidal power of the blood; this makes the method of treatment safe, as an increase in the power can be accepted as evidence of progress.

The series of cases which are described have all received individual treatment and supervision. General treatment was first applied by irradiation with mercury-vapour lamps; at a later stage when slight pigmentation was evident, exposure to two long-flame arc lamps was added to the treatment.

Debility.

Debility accounted for a large proportion of the cases treated. Many of the patients gave a history of previous acute illness—e.g., influenza, colds, and catarrh; in others there was evidence of susceptibility to colds. Although many had no signs of organic disease, the subjective symptoms—i.e., fatigue, weakness, and general malaise, generally demonstrating a subnormal state of health, were the chief reason for treatment. The average number of treatments per case was 13·3. So far as clinical results of treatment can be assessed by personal observations, the general tonic effect of radiation was evident in many patients. They usually said they felt brighter and more energetic, and often that their skins felt warm and glowing and able to withstand cold. Some patients, however, described a feeling of lassitude and drowsiness with an inclination to sleep. Since there are no definite physical signs obtainable to assess the results of treatment, personal subjective observations must be accepted. In cases of severe debility following acute illness the treatment appeared to hasten speedy recovery and return of vigour and health. A low hæmoglobin percentage was obtained in 18 cases, and all these showed an increase of hæmoglobin after 12 treatments. The average percentage before treatment was 66·2 and 82 after 13·9 treatments.

Skin Diseases.

Cases of eczema, acne, alopecia, and early psoriasis have shown the best results. A short course of general exposure by "short ray therapy technique," usually 4–6 treatments, was given before intensive treatment—i.e., a full erythema dose over the lesion every 10–12 days. The erythema persisted for four to five days, and desquamation of the skin occurred after six to eight days. When the skin lesions were diffusely scattered over the whole body, different areas were selected for intensive treatment once or twice a week, but treatment was never reapplied to any given area until all signs of desquamation had disappeared. Ichthyosis showed an excellent response, and cases of complete alopecia of many years' duration improved, four having almost completely recovered after 18 months' progressive treatment.

Tonsillitis and Sinusitis.

General exposure to light by "short ray therapy" improves the general body health and the anæmia and debility which are associated with subacute inflammatory diseases. Catarrh is lessened and the œdema and congestion of tonsils and pharynx are diminished. Local treatment to the mucous membrane and tonsils is indicated in cases of chronic catarrhal inflammatory conditions with recurrent acute attacks. The treatment has proved beneficial in lessening the susceptibility to colds and acute bronchitis. Treatment is indicated: (1) as a general tonic following the debility and toxæmia associated with septic throats; (2) to improve the general health before tonsillectomy or drainage of maxillary antrum; (3) to heal septic tonsils and discharging sinuses; (4) to diminish the frequency of colds and bronchitis. Local treatment of the pharynx, tonsils, and mucous membrane by the water-cooled throat lamp should only be applied in chronic conditions; in active acute inflammatory conditions it may give rise to a spreading acute cellulitis.

Asthma and Bronchitis.

General treatment has been beneficial and has hastened the healing of cases of active bronchitis. Some cases of bronchial asthma have reported definite improvement. The treatment is of great help during the cold, wet winter months, and assists many patients with chronic emphysema and bronchitis to carry on with their routine work. Cases of debility and bronchitis in young children have responded well.

Lumbago, Arthritis, and Chilblains.

A full erythema reaction over the dorsal lumbar region has in some cases greatly benefited cases of lumbago. Beneficial results have only been obtained in early cases of arthritis. The condition of fibrosis and thickening of synovial membranes with effusion have not shown improvement. The exposure of the hands or feet to intensive radiation has completely cured chilblains by improving the capillary circulation. The continuation of the treatment lessened the incidence of recurrence during the cold weather.

Tuberculous Diseases.

Lupus Vulgaris.—Early cases of lupus vulgaris are healed by general irradiation of the skin. All cases were given general irradiation in addition to periodic local treatment at the site of lesions. Chronic cases in which there was much fibrosis, scarring, and hypertrophy of granulation tissue proved most resistant. Before local treatment, the skin was carefully prepared and cleaned so as to remove dead cells, scales, and scabs. The application of a diathermy needle to isolated fibrous nodules was helpful. In one chronic case a "light sensitiser" (eosin) was injected locally; this caused intense reaction and a slow-healing ulcer. The result was favourable, and the method appears to be indicated in the most resistant types of lupus. If the treatment was continued long enough, in some cases for many months, all cases of lupus completely healed.

Glands.—All cases were treated by general irradiation; local treatment was only applied to discharging sinuses and soft caseous glands. Careful dosage of local irradiation at first caused swelling of the glands, followed by softening and increased discharge, and finally by healing. This inflammatory reaction and increase in size was often seen in the early stages of general treatment, but none of the glands broke down and suppurated. Periadenitis was lessened, and the glands became smaller in size, discretely isolated, and freely mobile. Fibrosis and healing of glands was obtained in all the cases selected, together with marked improvement in the general health with increase of weight, appetite, and general appearance.

Lungs.—The cases selected were chronic, "organised," non-pyrexial types of tuberculous disease. During the early stages of treatment expectoration was increased, and rest in bed after treatment was prescribed if there were symptoms of fatigue or malaise. The patients have improved and have kept well during the past year.

Larynx and Palate.—Tuberculous disease of the palate, tonsils, pharynx, and larynx respond to irradiation favourably. Local treatment is indicated in all cases in which there is no serious lesion of the lungs. Early cases heal with great rapidity. General irradiation of the skin two to three times a week and local treatment of the lesions was applied every 10 to 12 days. Patients were rested for 24 hours after local treatment, as a general reaction sometimes occurred. The technique of treatment with the special throat lamp has already been fully described.[6] The results are very satisfactory, and so far all cases have healed completely, except one case in which there was disseminated tuberculosis of the lungs. Tuberculous disease of the mucous membrane heals with greater rapidity than tuberculous disease of the skin.

Acute Pyrexial Microbic Infections and Granulating Wounds.

Small areas of skin, equivalent to one-twelfth of the surface area of the body—i.e., front of one leg—were exposed daily to a mercury-vapour lamp, and the minimal erythema dose was controlled by tests of the bactericial power of the blood. In all cases tested the initial bactericidal power of the blood was high, and an increase was observed after irradiation. If the hæmobactericidal power had decreased after irradiation treatment would have been discontinued. Lassitude, drowsiness, and sleeping were common after treatment, and in some cases a slight rise in temperature was attributed to the irradiation. Treatment was not applied when the temperature was high. More clinical evidence is necessary before definite conclusions can be recorded.

The improvement of general health by general treatment and local irradiation hastened the repair of granulation tissue and discharging sinuses after surgical operation. The most favourable results were obtained in the treatment of granulating wounds after radical mastoid operations.

Conclusions.

Light ray therapy is a painless method of treatment, which can be carefully controlled during the whole period of illness by cautious technique and correct dosage. Compared to other methods of treatment, such as radical surgical operation, scraping, or curettage, painting with strong acids, caustics and cauterisation, successful results of treatment of some tuberculous diseases by radiation therapy are a wonderful triumph. The treatment needs no anæsthesia, and causes little pain, and patients can often safely continue their normal routine during treatment. The scar tissue which follows healing of ulcers and granulation tissue is soft and freely mobile, and has a characteristic "white tissue-paper" like structure; telangiectic and keloid scars are unknown. The rapid healing of extensive tuberculous and other pyogenic chronic ulceration of the palate and fauces by means of this therapy decisively proves its curative power.

HOSPITALS AND ROAD ACCIDENTS.—The Ministry of Health and the Royal Commission on Transport have informed Mr. W. Renshaw, of the Altrincham Provident Dispensary and Hospital, that the position of hospitals in regard to the treatment of cases arising from road accidents "shall be taken into consideration." Mr. Renshaw is asking hospital secretaries all over the country to inform him of the number of such cases treated in 1928, their cost, and the payments made by the patients concerned.

THE IMPORTANCE OF THE LIVER IN CHEMOTHERAPY.*

WITH SPECIAL REFERENCE TO THE TREATMENT OF MALIGNANT DISEASE.

BY L. CUNNINGHAM, M.B. CAMB., M.R.C.P. LOND.,
HONORARY ASSISTANT PHYSICIAN, DAVID LEWIS NORTHERN HOSPITAL, LIVERPOOL;

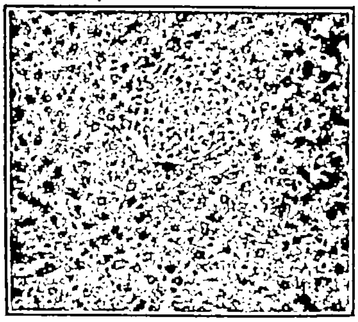
AND

M. M. DATNOW, M.D. LIVERP.,
CONSULTING GYNÆCOLOGIST, CLATTERBRIDGE INFIRMARY; CLINICAL ASSISTANT TO THE GYNÆCOLOGICAL DEPARTMENT, ROYAL INFIRMARY, LIVERPOOL.

WHEN we come to consider the variety of its functions it is evidently no mere accident or caprice of Nature that the liver is the largest organ of the body. Its portal circulation brings it into intimate relationship with the gastro-intestinal canal and spleen, so any blood changes occurring in these organs must act with particular intensity on the liver. The fact that all the material that enters the blood from the stomach, the small intestines, and the proximal part of the large intestine must pass through the liver before it enters the general circulation, helps to protect the body from toxic substances that may be absorbed from the intestinal canal. Some are converted directly into atoxic material, as when ammonium salts are converted into urea. Others combine with glycocoll, sulphuric acid, or glycuronic acid, and are thereby deprived of poisonous properties. Lastly, alkaloidal and mineral poisons are, to a certain extent, removed from the blood during their passage through the liver, and, as Willcox[1] states, as many others have done, this organ must be regarded as the first line of defence in all cases of generalised poisoning. The importance of the part played by the liver in carbohydrate metabolism, in the contribution of fibrinogen to the blood, in anaphylactic shock, in the secretion of bile, and the absorption of water is well established.

The toxic effect of arsenic on the liver has been the source of great concern to those employing the substance therapeutically. Foulerton[2] was among the first to call attention to the possible harmful effects of the arsenical compounds as essentially identical with poisoning by chloroform, ether, trinitrotoluene, and phosphorus. He experimented with rabbits and found an interstitial hepatitis with injury to the parenchyma cells and, in addition, nephritis. Clinically the toxic effects on the liver tissues and kidney may now be regarded as being among the most common of [illegible] ill-effects following the administration of [illegible]

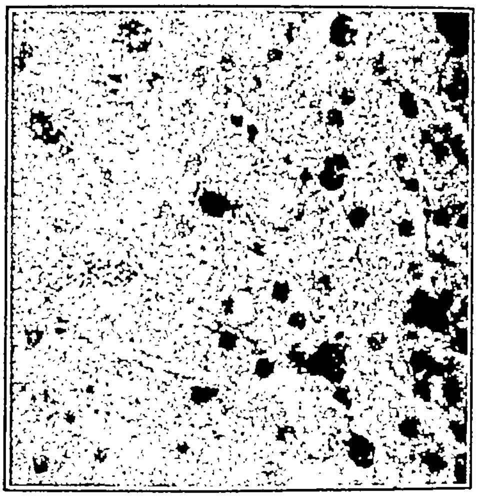
FIG. 1.



Liver from a rat treated with colloidal lead showing focal necrosis. (Microphotograph × 110. Prof. Carter Wood.)

MacCormac [illegible] investigated the liver function of [illegible] [illegible]rent stages of disease undergoing [illegible] [illegible]senobenzol. In 52 of these t[illegible] proper [illegible]rmal, and in the [illegible] out, any liver damage need not necessarily be due to the arsenic which is used, but may be caused by the syphilis which is being treated. There appears to be abundant evidence that every degree of jaundice and even acute yellow atrophy may occur in syphilis as an

FIG. 2.



Liver from a cat treated with colloidal lead showing particles of the metal in the Kupffer cells. (Microphotograph × 500. Prof. W. J. Dilling.)

accident of this disease, and perhaps, therefore, is in no way connected with the use of an arsenical preparation. On the other hand, arsenic when administered to patients for other conditions than syphilis has been known to cause definite derangement of hepatic function.

General anasarca following the ingestion of arsenic was recorded by Bang[4] as long ago as 1774. Geyer[5] reported the occurrence of wholesale poisoning from arsenic at Reichenstein, and mentions the frequent occurrence of serous effusion and ascites. Broadbent[6] made the interesting observation that the serous effusions occasionally seen in Hodgkin's disease might be attributable to the arsenic commonly employed in the treatment of this disorder. Rolleston[7] states that arsenic seems to be capable of setting up cirrhosis of the liver, mentioning in particular the Manchester epidemic in support of this view. O'Leary[8] reported undoubted examples of portal cirrhosis occurring in cases of chronic arsenical poisoning following the therapeutical use of potassium arsenite.

There is little doubt that many of the toxic effects of lead administered intravenously are in part due to liver damage. The varieties of pathological changes produced, especially in the experimental stages of the treatment of malignant disease with lead, have already formed an interesting study.[9]

When we consider the importance of the liver as an eliminator of lead it is not surprising that in industrial poisoning the rôle played by this metal in the production of hepatic lesions assumes considerable proportions. Several types of lesions of precirrhotic or cirrhotic character have been described. Potain[10] reports the occurrence of atrophy of the liver cells, fatty degeneration or infiltration, and intercellular or interlobar cirrhosis, and other observers add that small areas of exudation and hæmorrhage may also be seen.

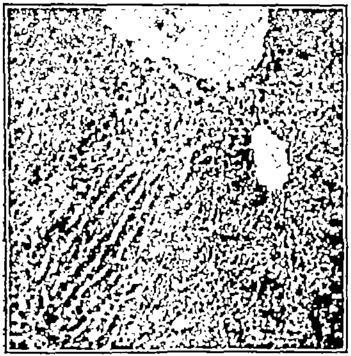
Kussmaul and Maier[11] believe that lead acts directly on the portal vessels, but Hanot and Charpentier[12] think that the hepatic cells themselves are chiefly affected. Meillère[13] states that periportal cirrhosis may be produced experimentally by lead, but Ophuls,[14] who worked with guinea-pigs, failed to observe this lesion.

[illegible] ho Liverpool [illegible] W. Blair

Seeligmüller [15] found evidence of hepatic cirrhosis in the liver of a new-born child of a lead worker, and recovered lead from the organ.

In spite of all the pathological conditions which have been noted in plumbism the consensus of opinion among pathologists who have studied lead poisoning is that post-mortem examination of the liver reveals no changes specific for lead. We ourselves have produced focal necrosis in the liver of rabbits that have received intravenous injections of lead, but no cirrhotic changes have been observed. Carter Wood [16] has demonstrated focal necrosis in the liver of rats by similar means (Fig. 1). Prof. Dilling [17] has shown that shortly after intravenous injections of colloidal lead the liver contains a considerable part of the metal which is distributed throughout the body. This observation is supported by those of other investigators. It must, however, be remembered that the route, frequency, and size of the dosage, and the time elapsing subsequently before the death of the animal, influence the final distribution of lead in the tissues. Dilling both estimated his lead quantitatively and demonstrated it microscopically. He found that the Kupffer cells appeared to contain large quantities of the metal (Fig. 2). This illustration shows the appearances of the Kupffer cells in the liver of a cat after intravenous injections.

FIG. 3.



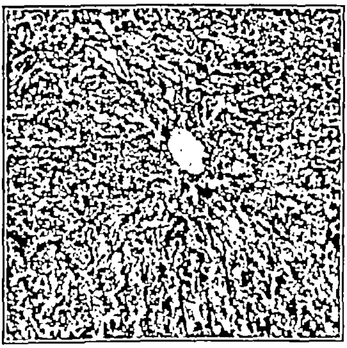
Liver from a rabbit treated with colloidal lead malate showing hæmorrhages into the liver substance. (Microphotograph × 110.)

The toxic effects of lead on the liver apparently arrange themselves into two groups: first, there is the general toxic or massive dose effect, similar to that which any toxin would produce if introduced into the blood stream, and which has been repeatedly demonstrated by many investigators. This can be produced by lethal doses of any lead preparation and is well illustrated in Fig. 3, which is a microphotograph of the liver of a rabbit treated with a large dose (60 mg.) of colloidal lead malate. Secondly, there is the delayed lead effect which can be produced by most preparations of lead if the dosage be controlled (Fig. 4). There is dilatation of the capillaries compressing the parenchyma cells, a condition which is general throughout the whole liver and is brought about by doses of lead preparations slightly larger than the amount required to produce abortion in pregnant does (a method of which use has been made in regulating the therapeutic doses of the various lead colloids prepared for the Liverpool Medical Research Organisation). If now more lead be given to the animal hæmorrhage will occur and the appearance will be similar to that in Fig. 3 described above. This is probably the explanation of the hæmorrhage mentioned by Legge and Goadby [18] in the livers from cases of lead poisoning.

With smaller doses, as employed in the treatment of patients, cloudy swelling results but rapidly clears up, and the liver is probably normal again in 24 hours. Substances like colloidal lead selenide, colloidal lead phosphate, and colloidal lead hippurate can be administered to rabbits in large doses (30 mg. per kg. of body-weight) without producing any effect other than cloudy swelling commencing around the central vein, the parenchyma cells in the neighbourhood of the portal systems being involved to a lesser extent or not at all. We suggest that if the lead had been administered by the mouth the portal areas might have been the first to degenerate, and would like to point out that in discussing the effect of lead on an organ like the liver, to which the blood arrives from distinct sources, it is essential always to bear in mind the portal of entry. This is so often overlooked by writers on the pathology of industrial lead poisoning and may perhaps be the explanation of the variety of changes described by different investigators. The period over which the lead has acted and the time when the post-mortem was performed should always be stated in drawing conclusions from particular histological appearances. The cloudy swelling may, of course, proceed to actual necrosis of the cells.

The fact that cirrhosis of the liver of the animals was not found is probably due to the fact that insufficient time had been allowed to elapse between the time of injection and that when the animal was killed. It seems quite probable that it would occur in the healing process after degeneration of the cells, but would not arise with the quantities employed during a course of treatment for malignant disease. In the livers examined histologically particles similar to those described by Dilling were constantly found in the liver cells.

FIG. 4.



Liver from a rabbit treated with colloidal lead aspartate showing the congested and dilated capillaries compressing the liver cells. (Microphotograph × 140.)

Clinical Manifestations.

Just as in the case of arsenic the obvious clinical manifestation of liver involvement in the course of treatment of malignant disease with lead, following the technique of Blair Bell,[19] is jaundice. With the increase of experience with regard to dosage and the interval between each dose we now see very little of this symptom, and it rarely attains any severity. It is very probable that a good many other symptoms, such as nausea and vomiting may be in part due to liver involvement. Table I., compiled from a series of 216 recent consecutive cases, illustrates the frequency of jaundice during treatment and the extent to which it is dependent on the nature of the preparation used.

TABLE I.

—	Number of consecutive cases observed.	Number developing jaundice.	Percentage developing jaundice.
S_7. Lead suspension (Pb = 0·5 per cent.)	172	19	11
L.S. Lead selenide (Pb = 0·2 per cent.)	19	2	10
H_9. Lead phosphate (Pb = 0·4 per cent.)	25	0	0

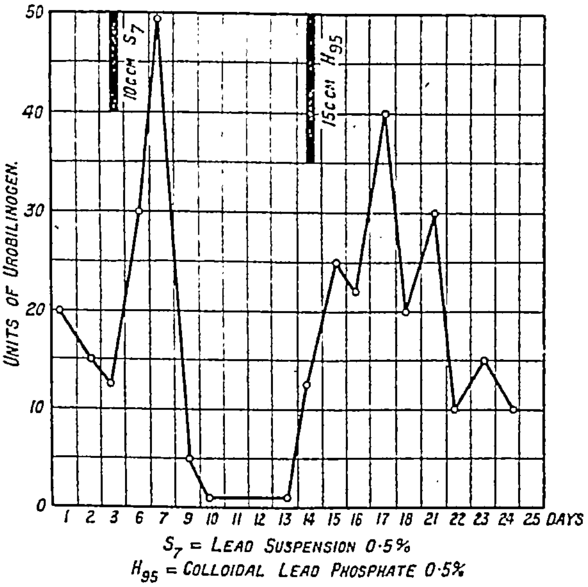
Tanquerel des Planches [20] in 1830 drew attention to two kinds of jaundice occurring in lead poisoning. He distinguishes "jaunisse suite des doleurs de colique" from "l'ictère saturnine, résultat de l'altération du sang par le plomb." The former he states to be due to extravasation of bile from its usual reservoir, and the other to a direct change of the blood by lead. This observation was amazingly accurate, and with our present knowledge of the reticulo-endothelial system is easy to explain.

In the early days of experimental lead therapy when larger doses were used three distinct types of jaundice presented themselves.

(1) A pure hæmolytic jaundice due to destruction of red blood-cells by lead and characterised by a fine icteric tinge, an indirect van den Bergh reaction, and excess of urobilinogen, but with no bile pigments in the urine.

(2) A type in which jaundice was deeper and in which a variety of van den Bergh reactions, including the biphasic, were obtained and along with which were found excess of urobilinogen and bile pigments in the urine. This type must have been associated with definite damage to the liver parenchyma.

FIG. 5.



The effect of intravenous colloidal lead phosphate on the output of urobilinogen.

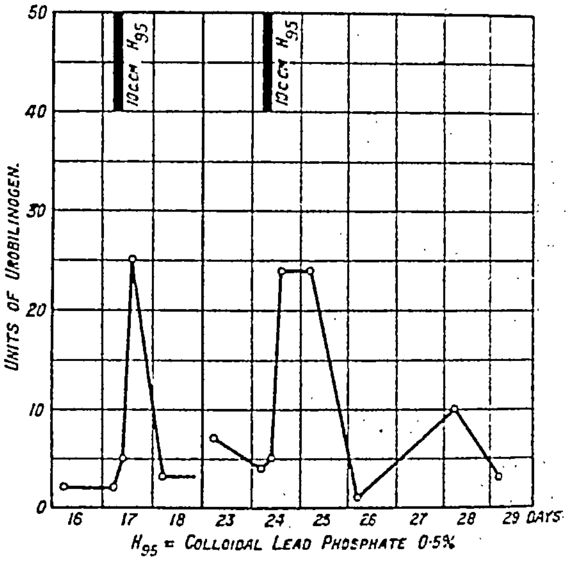
(3) A frankly obstructive jaundice where in addition to the changes in type (2) there must have been a cholangitis leading to obstruction of the smaller bile-ducts. In this type the jaundice is deep, bile pigments are present in the urine in large quantities, and the van den Bergh reaction is of the immediate direct type.

The majority of cases developing jaundice was apparently of the hæmolytic type and transient in nature, but the following case illustrates the rapid production of obstructive jaundice following a massive dose of lead suspension.

CASE N. H. 17.—Male, aged 24. Diagnosis, radiographic and histological, sarcoma of the femur.

Initial investigation revealed absence of anæmia and normal renal function. A massive dose of lead suspension (40 c.cm. of 0·5 per cent.) was administered intravenously at midday on Dec. 18th, 1924. The patient had a rigor lasting ten minutes at 6.30 P.M. and vomited three times. There was no diarrhœa. The following day there was marked diminution in the secretion of urine; hæmaturia, jaundice, and vomiting continued. On Dec. 22nd there was still oliguria, only 64 c.cm. of urine being secreted in 24 hours. The jaundice was deeper, there was bile in the urine, and the serum gave a positive direct van den Bergh reaction. By this time the blood-urea had risen from 23 mg. to 167 mg. per 100 c.cm. and the hæmoglobin had dropped from 98 per cent. before treatment to 38 per cent. after. On the following day the jaundice was less deep but persisted in some degree until the patient's death on Jan. 1st, 1925.

FIG. 6.



The effect of intravenous colloidal lead phosphate on the output of urobilinogen.

Output of Urobilinogen.

The consensus of opinion is that bacteria in the intestine convert bilirubin into urobilinogen. Most of this is excreted by the gut, but some is carried to the liver by the portal system and so reaches the liver parenchyma. The absorbed portion is largely reconverted by means of the liver cells and re-excreted with the bile; a small portion remains unchanged and is excreted in the urine. This conversion by the liver of most of the urobilinogen into bilirubin is important, in that many observers regard excess of urobilinogen in the urine as evidence of a damaged liver which is unable to bring about the conversion. MacCormac and Dodds [3] conclude that if there be any damage to the liver cells this property of converting urobilinogen into bile pigment is lost and, therefore, urobilinogen accumulates in the blood and is excreted in excess in the urine.

Uvedale Owen [21] has drawn attention to a fact which had escaped the attention of some observers—namely, that the output of urobilinogen varies from hour to hour and from day to day in the same individual. We have been able to confirm this observation and further to note that such factors as ketosis and intestinal stasis tend to increase the output of urobilinogen in the urine. Bearing these limitations in mind we have found the output of urobilinogen in the urine to be a valuable guide to the probable extent of liver damage, the result of lead therapy.

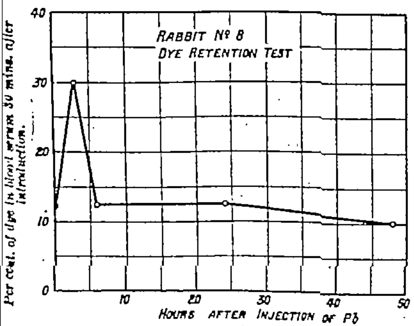
ndeed, we have considered a high urobilinogen ontent of the urine as the result of lead therapy to e a contra-indication to further dosage until more ormal values have been obtained.

The quantitative test we have used is a modificaion of that of Wallace and Diamond [22] who used hrlich's aldehyde reagent which produces a red olour with urobilinogen. The effect of lead therapy n the output of urobilinogen is shown in the following two charts of patients who are undergoing treatnent (Figs. 5 and 6). Each morning the amount of robilinogen in the urine is estimated and in some ases each specimen that is passed for 24 hours or 8 hours as in Fig. 6. The immediate rise corresponds closely with the period of maximum dye etention in rabbits following injections of lead hich will be described later. Occasionally no rise n the urobilinogen output occurs, and it is these ases which show but little tendency to develop toxic nanifestations.

Dye Retention.

The dye-retention test was devised by Rowntree, Hurwitz, and Bloomfield,[23] who noted that phenoletrachlorphthalein, when injected subcutaneously, scaped from the body exclusively via the biliary assages. By careful animal experiments the origiators of this test were able to prove that the excretion f the drug diminished in proportion to the amount f liver tissue damage. Since this work various mprovements have been suggested both in the nethod of administration, nature, and dose of the dye. Graham and Cole [24] inject 40 mg. of phenoltetraodophthalein per kg. of body-weight intravenously, hereby taxing the liver to its utmost with a relaively toxic but brilliant dye, estimating the amount f dye left in the blood after half an hour. They ave found that by using this amount it is possible to estimate smaller variations in extent of liver damage than can be found by using the lesser quantities of phenoltetrachlorphthalein and bromsulphthalein.

FIG. 7.



The effect of intravenous lead suspension on dye retention in a rabbit.

In our experiments we have used both the bromsulphthalein as recommended by Bulmer[25] and more recently phenoltetraiodophthalein, adopting the method of Graham and Cole and following their technique in every detail. Our experiments were divided into two groups: in one group the dye retention in rabbits following lead (S_7) injections was determined, and in the other group the effect of lead on the dye retention was estimated in patients undergoing treatment with this drug.

Table II. and Fig. 7 illustrate the effect of lead in the form of S_7, which is a suspension containing 0·5 per cent. of lead, on the dye retention of rabbits.

It will be noticed that the highest rise occurs about three hours after the injection, but that a rise is frequently observed also on the day following injection and that this tends to return to normal after two or three days. In the case of patients undergoing treatment with lead—that is, with relatively smaller doses than were given to the rabbits—no difference was observed in the dye retention either in the case of bromsulphthalein or phenoltetraiodophthalein.

29/11/28	—	—	10	24 hours

* No positive van den Bergh reactions were ever obtained. This rabbit was very ill 24 hours after the lead administration and had to be killed. Histological examination of the liver showed definite liver damage. This will account for the increased dye retention when the test was carried out before the animal was killed.

Lævulose Tolerance.

The lævulose tolerance test as described by Spence and Brett [26] has been of no value to us in determining the extent of liver damage the result of lead therapy. It has, however, been useful in determining the suitability of cases for treatment with this drug in the initial investigation of the patient. One of the causes of its failure is the fact that nausea and vomiting, which the ingestion of large quantities of lævulose may produce, militate against the success of this procedure and these are of necessity a frequent accompaniment of a damaged liver.

Conclusions.

The conclusion we have come to in the observation of the toxic effects of the injection of colloidal lead is that a careful study of the existing damage to the liver in the course of treatment, so far as this is possible, is of importance in the determination of the extent and interval of dosage. A careful examination of the liver function is of great importance also in the initial selection of cases, for we cannot hope to treat a case successfully with lead where the liver function is even moderately impaired.

CONGENITAL ECTODERMAL DEFECT.

BY A. W. FALCONER, C.B.E., D.S.O.,
M.D., M.R.C.P. LOND.,
PROFESSOR OF MEDICINE, UNIVERSITY OF CAPE TOWN,
SOUTH AFRICA.

IN 1920 Goeckerman[1] reported a case of a patient who presented more or less aplasia of most of the cutaneous ectoderm. He discussed six similar cases in the literature and considered they formed a distinct and easily recognisable type. He applied to them the term high grade or major ectodermal defect.

MacKee and Andrews[2] described a similar case. After a consideration of the literature they came to the conclusion that various grades of congenital aplasia of the skin, nails, hair, and teeth, and even of the subcutaneous and sweat glands, alone or in combination, are of fairly frequent occurrence, but that it is much more uncommon to meet with patients presenting congenital anomalies, ranging from deformation to complete absence of all the cutaneous structures originating from the epidermis. Goeckerman, in the discussion on this paper, referred to a further case seen by him, and stated that Jhadani, of India, had seen many of these cases as a hereditary, generally sex-linked, anomaly transmitted through the mother. Goeckerman's own case was in a female though all the other recorded cases were in males.

MacKay and Davidson[3] record a family, which they include under this group, showing a minor degree of ectodermal defect without involvement of the teeth, sweat or sebaceous glands. In this family the condition had shown itself in five generations and occurred in both males and females. As is usual with hereditary conditions in several of the cases no history of a familial incidence could be obtained. Jean Smith,[4] under the term abnormal dentition, showed a case in a male child of 5 years of age, markedly under weight, with dental aplasia, hypotrichosis, absence of sweating, and a history of a previous admission to hospital when 3 months of age with a temperature of 107·8° F. which rapidly fell and for which no cause could be detected, which apparently belongs to this group.

The main clinical characters described by MacKee and Andrews are as follows:—

1. A dry, white, smooth, thin, pliable, and glossy skin. In their own case there were numerous fine wrinkles at the corners of the eyes and on the cheeks near the nose.

2. Absence of sweat glands. None of the recorded cases had ever shown sensible perspiration, and histological examination which had been carried out in the majority of the cases failed to show sweat glands or anlage.

3. Dental aplasia to a pronounced degree was found in all the recorded cases. The case described by MacKee and Andrews had five teeth, the largest number recorded, including one in the lower jaw which is unusual as in all the other cases the lower teeth were absent.

4. Hypotrichosis. Congenital hypotrichosis is common to all the cases, the hairy parts being involved in various degrees. Lanugo hair is absent from most of the body surface.

5. The lips are thick, muscular, and everted, presumably the result of the additional labial activity required for mastication without teeth.

6. Depressed nasal bridge and chronic atrophic rhinitis. A depressed nasal bridge and prominent frontal bosses were present in all the recorded cases. In the great majority there was a chronic atrophic rhinitis.

The case described below is peculiar in that the bridge of the nose is not depressed.

7. In several cases the nails were deformed.

8. Papular lesions of the face are recorded in a considerable proportion of the cases.

9. Inferior mentality has been recorded in several of the cases, in others the mentality has been normal or somewhat above normal.

10. Patients are handicapped through inability to radiate sufficient heat under certain environmental conditions, but they are healthy and active and longevity is apparently unaffected.

In Tendlan's case[5] the mammæ were absent.

Subjective Symptoms.—The main subjective complaint which is common to all patients is discomfort in hot weather. They find it necessary to avoid heat, vigorous physical exercise, hot food and drink, especially in hot weather, and often are compelled to resort to artificial perspiration by keeping their clothes wet with water.

A New Case.

The following case was admitted to hospital under my care in July, 1924, and has been under intermittent observation ever since:—

V. J., male, aged 6¼ years. Complaint: absence of teeth, hair, and sweating, with great discomfort during the hot weather.

Patient was born at full time after a difficult labour. He weighed 5½ lb. at birth. During the pregnancy the mother vomited incessantly but her general health did not seem to suffer much. He was breast fed for two months, but as he was extremely thin he was put on lactogen and later other foods. Nothing seemed to disagree with him but he remained extremely thin. At 9 months of age he developed a cough accompanied by hoarseness, and ever since then he has had periodic attacks of hoarseness. Up to 18 months of age he had no hair on his head or body, but at 18 months he began to show some downy hair on his head and a little on his body. He began to walk and talk at 18 months and at 2 years he cut two teeth in the upper gum, one on each side far back. An X ray taken at this time was said to have shown no evidence of further teeth. He had had various forms of ductless gland treatment, chiefly thyroid, but his mother always stopped them as they caused mental excitement. He was born and lived in Zululand, and ever since birth he had been very uncomfortable in hot weather and had never been seen to sweat. He managed to get through the hot weather by the use of frequent cold baths and keeping his hands and feet in cold water. Apart from the discomfort during the hot weather and the periodic attacks of hoarseness he had been well.

Family History.—There are two other children—4 and 6 years older than the patient. There have been no miscarriages. They are both perfectly well-developed and normal children. The mother is a well-developed woman. The father is rather small and thin. Recently (1929) he is reported to have developed tabes dorsalis. There is no known similar case on either side of the family.

On admission to hospital (June 9th, 1924) the boy's appearance (Fig. 1) simulated very closely a

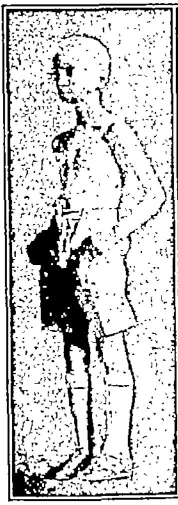
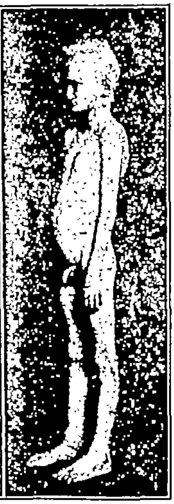
diminutive old man. He had a large globular head very scantily covered with an almost colourless down from 1 to 1½ inches long. There were numerous prominent veins all over his head. There was a complete absence of eyebrows; the eyelashes were present in moderate amount, but as they were almost colourless, they were not seen at first glance. Over the upper part of the face were a few scattered cream-coloured papules, the largest about the size of a large pin. Running horizontally backwards from the outer canthus were numerous fine wrinkles, and similar wrinkles were present from the inner canthus running down the cheek and at the angles of the mouth. The nose was straight and not depressed. The lips were relatively thick and everted. The lower jaw was very poorly developed. The alveolar margin was thin and sharp, not much thicker than the blade of a knife. There were two teeth, one on each side of the upper jaw for back. An X ray shows no evidence of further teeth.

FIG. 1.



Patient, aged 6½ years.

FIG. 2.



Aged 7½ years.

The whole lower half of the face was tiny compared with the upper half. The body was extremely thin; there was a complete absence of breasts and the nipples were represented only by a minute pigmented spot. The whole skin was dry but not harsh except on the palms of the hands, where the skin was thick, cracked, hard, and dirty. There was on the limbs a very scanty, very fine down-like hair. The genitals are underdeveloped, the testicles being about the size of small cherry stones.

Radiological Appearances.—X ray of the skull showed a normal sella turcica. The bones of the vault of the skull were very thin. X ray of the limbs showed ossification normal for his years. There was no cardiac enlargement.

The blood pressure was 100/62. The urine showed no albumin or other abnormal constituents. There was a distinct polyuria varying from 50–80 oz. per day. The urea-concentration test at the second hour showed 2·45 per cent. The two-hour test showed a variation of 10 in the specific gravity and no increase of nocturnal urine. The blood-urea was 30 mg. per 100 c.cm., creatine 1·75 mg., uric acid 2·3. A blood-sugar curve was normal. The basal metabolic rate was on first admission estimated at +15 per cent., a year later at −6 per cent.

Dr. J. Luckhoff, in charge of the nose and throat department, reported:—

> "The upper jaw though with an ill-developed alveolar margin is shallow but very broad, consequently the nasal spaces are quite abnormally wide, the turbinate bodies are relatively small, and the mucous membrane dry with a secretion of yellow tenaceous muco-pus—a pathological condition clinically (though not typical) very similar to the disease we term atrophic rhinitis. Relative to the size of his nasal spaces his maxillary sinuses are not large, his frontal sinuses are very small. Larynx shows a typical laryngitis sicca secondary to the nose condition. Mastoid processes both in surface bulge and in length are abnormally developed with a deep sulcus between them and the meatus on each side. The skull bones seem thin."

The Wassermann reaction was negative. Mentally the boy was bright and, possibly because he had never been to school on account of his peculiar appearance, precocious. In 1929 his appearance had improved and he is now attending school and doing quite well. His mother states that he has already had several articles or children's stories published in the newspapers.

Pilocarpine up to one-sixth of a grain, followed by a hot pack, produced no visible perspiration.

Readmission.—The patient was readmitted again for examination in April, 1925. His appearance had distinctly improved and he looked decidedly younger (Fig. 2). There was an increased growth of hair on the head and there was definite evidence of eyebrows. He was still very uncomfortable in hot weather, but thinks he sweats a little now. After pilocarpine, gr. ⅙, although no visible sweat was apparent, on palpation there did appear to be some moisture on the skin. The physical examination was as on previous examination except that the knee-joints were rather more prominent. There was no pain but there seemed to be slight effusion in both joints. The testicles did not appear to have developed much.

There was much difficulty in getting permission to excise a portion of skin for examination, but since the patient had a small wart on the thenar eminence of one hand, this was removed with a portion of the surrounding skin. Prof. B. J. Ryrie reports on it as follows:—

> "The sections show a papilloma with 0·6 to 0·75 cm. of the surrounding skin on either side of it. The line of excision is sufficiently deep to bring all layers of the skin and part of the subcutaneous fatty areolar tissue under examination. The epidermis shows well-marked differentiation into the various layers. Stratum granulosum is very marked and there is a high degree of keratinisation. Corium and subcutaneous tissue appear normal and the fine muscular fibres are well developed. Epithelial skin appendages are entirely absent, there being no hairs, no sebaceous glands, and no sweat glands."

The patient was seen again in June, 1929, although there was no opportunity to overhaul him. He had still further improved; the hair on his head had grown still more, and his mother considered him much better.

Discussion.

Except for the fact that the bridge of the nose is not depressed and that the sexual development is backward the case corresponds exactly with those described by Goeckerman and MacKee and Andrews. With regard to the ætiology there seems no doubt that the condition is a true hereditary developmental defect frequently familial, the arrest of development occurring very early in intra-uterine life. Although the present case is, in view of the father's tabes, possibly a congenital syphilitic, there is no evidence in the other cases that syphilis plays any part in the ætiology.

A further interesting and practical point is the similarity in appearance, at any rate, in the early stages of some of these cases, to the clinical picture described by Hastings Gilford as progeria. Although this was not remarked upon in any of the cases collected by MacKee and Andrews, the appearance of the present case when first seen in 1924 closely resembled the photograph of Hastings Gilford's Case 1 at 15 years of age and also his reproduction of Variot's case.[6] There was the same leanness, the same absence of hair, the wrinkling of the skin of face about the eyes and nose, the general dryness of the skin, the thin skull with visible veins coursing over it, the relative smallness and shortness of the lower part of the face accentuated by the ill-development of the alveolar portions of the jaw, and the absence of teeth. There was also the backwardness of sexual development. It is true that the lips were thick, but this could reasonably be accounted for as the result of muscular hypertrophy on account of the complete absence of teeth. The nose was thin and short. A diagnosis of progeria had actually been made.

In the discussion on Dr. Jean Smith's case shown at the Section for the Study of Disease in Children of the Royal Society of Medicine under the term abnormal dentition, Dr. Kingston Barton remarked on the facial resemblance to progeria, and Dr. Jean Smith stated that progeria had been at first suggested as the diagnosis but had apparently been ruled out on account of absence of cardiovascular changes and the lack of a dry withered skin.

Resemblance to Progeria.

It is of interest also that Gilford's Case 2 was first described by Hutchinson when 3½ years old as "congenital absence of hair and mammary glands with atrophic condition of the skin and its appendages in a boy whose mother had been almost wholly bald from alopecia areata from the age of 6." Hutchinson further described the nails as thin and curved backwards so as to present more or less of a hollow in the middle. Although Hutchinson described the teeth at the age of 3½ as all cut and tolerably regular, Dr. Jago, in describing the condition at the age of 14, ated "the teeth are abnormal in number, none are cayed, nor have any been lost or extracted. The anines, bicuspids, and incisors are normal but somewhat irregular, but there are no molars."

In Gilford's Case 1 the mammary glands also were absent, and unusually small nipples were present. The nails were very short, flat, ill-shaped, and membranous. The teeth were few in number, crowded, and erratic in situation and variable in size. The skin was soft and pliable and usually dry, although Gilford was able to detect sweat twice in hot weather. Gilford in 1911 looked upon progreria as a premature senile decay affecting the body as a whole, arising in an individual in a state of infantilism. He did not consider the evidence sufficient at that time to implicate the pituitary. He did, however, differentiate the senile appearance frequently presented at a somewhat later age by ateliotic dwarfs from true progeria.

Simmonds [7] described in adult women following embolic destruction of the anterior lobe of the pituitary the onset of cachexia, greying of the hair, loss of the axillary and pubic hair, wrinkling of the skin, loss of teeth, and a general appearance of premature senility. Later he reported [8] the case of a dwarf, 110 cm. in height, who died at the age of 21. At autopsy the posterior lobe of the pituitary was normal, but there was almost complete destruction of the anterior lobe with replacement by cysts which Simmonds considered the result of an embolism. It is noteworthy that, although he had already described moderate grades of apparent premature senilism in adults the result of embolic destruction of the anterior lobe, he makes no mention of its presence in this case.

Harvey Cushing [9] definitely accepts progeria as a pituitary syndrome. He publishes a remarkable photograph of a female, aged 8, as an example of the Hutchinson-Gilford syndrome of progeria. It differs, however, very strikingly from the Hutchinson-Gilford cases in the fact that she possesses well-developed eyebrows and an excellent head of coarse black hair. The shape of the lower part of the face is also quite different from the ill-developed lower jaw of progeria. The whole appearance of the case is much more suggestive of Gilford's ateliotic dwarfs with consecutive senilism which he definitely differentiated from progeria. Examples of this correlation he figures on pages 663 and 693 of his book.

It seems clear that anterior lobe deficiency commencing at an early age may lead to various degrees of dwarfing with infantilism and a more or less striking appearance of premature ageing, but these cases differ materially in appearance from the cases described by Hastings Gilford as progeria. In these cases an essential feature seems to be a more or less extensive ectodermal defect which in itself gives a peculiar aged appearance to the individual. In Gilford's Case 1, as in the present case, the nipples were completely absent, and this must have originated in an early stage of intra-uterine development. In other cases a similar ectodermal defect occurs as a hereditary anomaly without progressing to the visceral and vascular changes accompanying the full-blown picture of Gilford's progeria. Clinically in their early stages some of these cases simulate to a remarkable extent the appearance of Gilford's cases.

Should such a patient become affected with a chronic nephritis, to which he might be considered unduly liable on account of the frequency of chronic septic infections of the nose and the increased strain on the kidney from the defective sweat apparatus, his condition would certainly be indistinguishable from one of progeria. It might be suggested that the ectodermal defect in progeria included the pituitary; but of this there is no proof, and in both Gilford's cases at autopsy the pituitary, although not examined with the care that would now be devoted to it, was stated to be normal macroscopically both in size and appearance.

Clinical and Laboratory Notes.

PROGNOSIS IN MALIGNANT MELANOMA.

A REPORT ON FORTY CONSECUTIVE CASES.

By Humphrey H. Gleave, M.B. Leeds,
M.R.C.P. Lond.,
LECTURER IN PATHOLOGY IN THE UNIVERSITY OF SHEFFIELD;
LATE DEMONSTRATOR OF PATHOLOGY IN THE
UNIVERSITY OF LEEDS.

During the 15 years 1910–24, 40 cases of malignant melanoma were examined in the pathological department of Leeds University, 22 arising in skin or mucous membrane and 18 in the eye. Thirty-six of these came from the Leeds General Infirmary, one from the East Leeds War Hospital, one from the Women's Hospital, and two from private sources.

Incidence of the Disease.—The in-patient admissions at the infirmary during this period were 136,600 and 36 cases of malignant melanoma were reported. However, as some of these patients were treated in the out-patient department the incidence is even less than the figures shown.

Age and Sex Incidence.—Of the eye cases there were 13 males and five females, the average age being 58·4 years. Of the skin cases there were seven males and 15 females, the average age being 56·3 years. The youngest patient was aged 27, the oldest 82. These figures may be compared with those of Broders and MacCarty (1916), who found an average age of 49 in a series of 70 cases. The Leeds figures suggest that the age incidence for eye and skin cases is the same.

Subsequent History of Cases.

1. *Eye Cases.*—Of the 18 eye cases, 15 have been traced. Five are alive and well after periods ranging

from 5 to 10 years. Three died within one year of operation, three within two years, and one each at seven, eight, and nine years. The cause of death could not be ascertained with certainty in all the cases, but several of the histories suggest the presence of secondary deposits. In the following three cases the presence of metastases was confirmed post mortem.

1. A man, aged 60, after having failing vision for two and a half years, was admitted for detachment of the retina with tumour. The eye was removed by Mr. A. L. Whitehead. Nine years later he was admitted under Lord Moynihan for intestinal obstruction, due to a large melanotic growth involving the sacrum and rectum. At autopsy the liver was found to contain a few tertiary deposits.

2. A man, aged 67, had had six weeks' history of eye trouble previous to removal of the eye (Mr. Whitehead). Thirteen months later, at autopsy, secondary deposits were found in liver, lungs, and pancreas.

3. A third man had a blind eye for 11 years. He first attended the infirmary for symptoms of malignant disease of the liver (Dr. Wardrop Griffith). Post mortem extensive deposits of malignant melanoma were found in the liver and peritoneum, and a primary tumour in the eye.

These cases illustrate the varying malignancy of the growth, and the last the remarkable latency which has been observed so often. Cairns (1923) reports a melanoma of the scapula secondary to a tumour of the eye removed 18 years previously.

2. *Melanoma of Skin and Mucous Membranes.*—The sites of origin were as follows. Eyelid 1, cheek 2, parotid region 1, neck 1, trunk 6, thumb 2, forearm 1, buttock 1, instep 1, great toe 2, anal canal 1, vulva 1, gum 1. In one case the tumour was found in a gland of the groin, and no primary was ever discovered. A history of pre-existing pigmented moles is recorded in eight cases. Of 20 cases traced, two remain without recurrence after five and seven years respectively. Of the 18 who died, 12 are considered to have had metastases. In two this was confirmed at autopsy; in the rest, either the growth was incompletely removed at operation, or enlarged glands, ascites, &c., were observed before death. There was one instance of multiple secondary deposits in the skin. In two others the presence of secondary deposits at death is probable.

One of these patients had a growth of the great toe and enlarged glands of groin removed by Mr. Littlewood. Both primary and secondary showed microscopically a melanotic growth of epithelial type. He remained well for ten years, and then returned for examination, when he was found to have malignant disease in the groin glands and in the liver. There was no indication of a primary source other than the original tumour. The latency of malignant melanoma is apparently not confined to tumours arising in the eye.

Of the 18 patients, 7 died within one year of the first operation, 3 within two years, 4 within three, 2 within four, and 1 each at six and ten years. Trauma was noted in the case reports in four cases. (1) "A fall of coal caused a mole on the cheek" 20 years before the onset of malignancy. (2) The top of a mole on the back was knocked off by a cricket ball four years before malignant ulceration began. (3) A spark from an anvil injured the thumb, and "something was cut out" one year later. Seven and a half years later a melanotic tumour developed on the site with secondary deposits in the axillary glands. (4) A malignant melanoma developed on the site on a shrapnel wound of loin received eight months before. There had never been any moles on the site. The patient died four months later, and at post mortem Prof. Stewart found extensive metastases (liver, pancreas, testes, kidneys, heart, brain, bones, and gastro-intestinal tract). These cases may be compared with those of Eve (1903), where the tumour developed on the site of an injury received in one instance 20 years and in another 12 years previously. There is no record in this series of the probably more important factor of repeated slight trauma or irritation as emphasised by Dawson (1925), who noted in one case that simple repeated scratching of a mole was followed by rapid development of malignancy.

Comparison of Malignancy of Tumours of the Skin and of the Eye.—Out of 15 eye cases traced, five are alive and well, 10, 15, 18, 12, and 5 years respectively, subsequent to the removal of the eye. Out of 20 skin cases traced, only two are alive (toe five years, scapular region seven years). Taking deaths from all causes, it is found that ten eye cases survived operation for an average period of four years and two months, and 18 skin cases for two years and four months. Eve, judging from Lawford and Treacher Collins's cases of melanotic sarcoma of the eye, in which 20 out of 79 patients were alive three years after operation, states that the malignancy of this tumour is somewhat lower in the eye than in the skin. Broders and MacCarty report four eye cases in their series of 70 cases of melano-epithelioma, and reach the same conclusion. The lower malignancy of the tumours of the eye is probably not due to earlier treatment. These tumours metastasise by the blood stream, whereas the tumours of the skin usually affect the regional lymph nodes before generalisation. Protection of the eye from trauma and a less abundant blood-supply may be factors in the process. When metastatic or recurrent growth occurs, the rate of progress of the disease seems to be the same in both eye and skin cases. Thus in Lawford and Treacher Collins's series of 26 eye cases with secondary deposits the average duration of life after operation was two years and four months.

Total Duration of the Disease in Skin Cases.—The notes allow of an estimate of the total duration of the disease from the onset of malignancy (increased pigmentation of mole, increased growth or ulceration), in ten cases of melanoma of the skin with metastases. This period averages two years and ten months (shortest nine months in the case arising in a shrapnel wound, longest four and a half years in a melanoma of instep, both confirmed at autopsy). However, as mentioned above, one patient apparently survived 11 years in all. This finding is an agreement with Dawson, who states "the generalisation is said to average three years from the time of malignancy in the primary growth, but in my series it took place earlier in most of the cases."

Treatment.—The frequency of involvement of the regional lymphatic glands of malignant melanoma of the skin and the instance quoted of the patient who survived ten years after removal of glands invaded by growth, confirm the desirability of attacking the glands along with the primary tumour.

I am indebted to the honorary officers of the Leeds General Infirmary for permission to make use of their cases, and to Prof. M. J. Stewart for his interest and help.

THE USE OF
GLYCERIN IN CÆSAREAN SECTION

BY MARGARET SALMOND, M.D. LOND.,
SENIOR ASSISTANT, OBSTETRICAL AND GYNÆCOLOGICAL UNIT, ROYAL FREE HOSPITAL.

GLYCERIN is now recognised by obstetricians as a valuable drug. It is used for drainage in local uterine sepsis and for the control of postpartum hæmorrhage in deliveries by the normal route. Little, however, has been written about its use as a hæmostatic in delivery by Cæsarean section. This year, on the suggestion of Dame Louise McIlroy, it has been used almost as a routine in the obstetrical unit of the Royal Free Hospital and has been found to be most successful in controlling hæmorrhage. Glycerin is also valuable in that it promotes drainage of the uterus during the puerperium.

The technique is simple. After removal of the placenta the uterine cavity is swabbed out with gauze dipped in glycerin and held on a sponge holder. The uterus is wrapped in hot towels and the abdominal cavity and wound protected by mattresses. Retraction of the uterus nearly always follows at once.

It seems possible that this method may obviate the necessity for hysterectomy following Cæsarean section in the few cases where this is required, since it appears not only to control hæmorrhage but is of proven value in the treatment of local uterine infections. We have had no opportunity so far of testing this.

This method was used in the following seven cases, in all of which the classical operation was performed, the patients being in labour at the time of the operation.

CASE 1.—Primipara, aged 32. Antenatal condition normal; contracted pelvis. Labour, Jan. 29th, 1929: vertex presentation, membranes unruptured; one vaginal examination made. Cæsarean section for disproportion, hæmorrhage not excessive; glycerin used in cavity. Puerperium afebrile until sixth day when breast abscess developed.

CASE 2.—Multipara (2), aged 30. Previous children stillborn, died before labour began. Antenatal condition: toxæmia, poor general condition. Wassermann reaction negative. Admitted for some weeks before labour for rest and diet. Contracted pelvis. Labour, Oct. 22nd, 1928: vertex presentation, membranes unruptured; no vaginal examination made. Cæsarean section for disproportion; hæmorrhage very severe, controlled with the help of glycerine. Blood transfusion. Puerperium was febrile the first week. Temperature rose to 100·2° F. twice. Patient developed superficial abscess under left eye. Obstetrical condition satisfactory and no other cause found for pyrexia.

CASE 3.—Primipara, aged 27. Antenatal condition: *Bacillus coli*, pyelitis. Admitted for treatment; contracted pelvis. Labour, Nov. 25th, 1928: vertex presentation, membranes ruptured. One vaginal examination made. Cæsarean section for disproportion; hæmorrhage not excessive; glycerin and blue paint used in uterine cavity. Puerperium afebrile.

CASE 4.—Primipara, aged 22. Antenatal condition normal; contracted pelvis. Labour, Jan. 12th, 1929: vertex presentation, membranes unruptured; one vaginal examination made. Cæsarean section for disproportion; hæmorrhage profuse. Glycerin used—hæmorrhage controlled. Puerperium afebrile, involution somewhat delayed. Lochia normal. Glycerin drain on twenty-second day, after which uterus involuted normally. Toxic myocarditis.

CASE 5.—Multipara (2), aged 43. Previous children both stillborn after instrumental deliveries. Antenatal condition: toxæmic; admitted for rest and diet. Contracted pelvis. Labour, August 15th, 1929: vertex presentation, membranes unruptured. No vaginal examination made. Cæsarean section for disproportion; hæmorrhage fairly profuse, controlled by glycerin. Puerperium. Temperature 100·4° F. first night following operation, since afebrile.

CASE 6.—Primipara, aged 27. Antenatal condition normal; contracted pelvis. Labour, August 10th, 1929: vertex presentation; the patient ruptured her membranes four days before admission but had no pains and did not come to hospital; no vaginal examination was made. Cæsarean section for disproportion. Hæmorrhage profuse, controlled by glycerin. Puerperium was febrile for nine days. Maximum temperature 101° F. on seventh and eighth days. Lochia offensive. Glycerin drainage of uterus on eighth day. Temperature fell within 24 hours and has remained normal since.

CASE 7.—Multipara (2), aged 33. Previous children: (1) stillborn, (2) Cæsarean section for disproportion. Contracted pelvis. Antenatal condition normal. Labour, May 8th, 1929: Cæsarean section for disproportion, membranes ruptured; no vaginal examination made. Glycerin and flavine used in uterine cavity. Hæmorrhage not excessive; sterilisation performed. Puerperium. Temperature 101° F. once on the eighth day, otherwise afebrile.

The condition of all these patients and their infants were satisfactory on discharge. It is impossible to describe the rapidity with which retraction occurs when glycerin is used, but it is hoped that the account of these few cases will stimulate others to try this method for the control of hæmorrhage and for drainage of the uterus.

I am indebted to Dame Louise McIlroy for permission to publish these cases.

BRITISH MEDICAL ASSOCIATION.

ANNUAL MEETING IN MANCHESTER.

(Continued from p. 613.)

SECTION OF PUBLIC HEALTH.

MATERNAL MORTALITY.

Dr. R. VEITCH CLARK (Manchester), who presided over the discussions of this Section, said that maternal mortality was rather overshadowed by the mortality from the great killing diseases, but that it had an even more disastrous effect on family life. Maternal mortality had for its incidence only the child-bearing women, whilst tuberculosis had for its incidence the whole population. If we took the ratio of deaths to risk we should find that childbirth mortality was three times as great as that of any other killing disease.

The opening paper by Dr. J. PARLANE KINLOCH, chief medical officer, Department of Health for Scotland, was based largely on the conclusions arrived at in the Report on Maternal Mortality in Aberdeen, 1918–1927.[1] Dr. Kinloch submitted the thesis that with our present knowledge a significant reduction in maternal mortality would be immediately attained by an extension of adequate antenatal services and the institution of the new midwife-doctor combination defined in the report named. It had been shown that 90 per cent. of the deaths from sepsis were due to the hæmolytic streptococcus, on which attention should be concentrated. Prevention and treatment could not be separated because early treatment of puerperal sepsis involved isolation and the prevention of further cases of sepsis by contagion. One of the advantages of the notification of puerperal pyrexia had been the earlier discovery and treatment of sepsis cases. In consequence, during the four years for which pyrexia had been notifiable, the incidence of puerperal fever had increased from 3 per 1000 births prior to 1925 to 12 per 1000 births in 1928. This earlier discovery must have a profound effect on the efficacy of treatment.

Mr. J. BRIGHT BANISTER (London) thought there was a danger of going too fast in revolutionising the practice of obstetrics, and that acrimony should not enter into this great problem. He considered that autogenous infection was more common than some authorities would admit. Eclampsia and toxæmia could be greatly reduced by antenatal treatment. He favoured delivery in institutions, wherever possible, and thought this custom was one of the causes of the low maternal mortality in Scandinavian countries.

Prof. D. DOUGAL (Manchester) said there had been much needless exaggeration which might almost lead one to believe that the process of coming into the world was as fatal as the process of passing out of it. It was, however, true that with our present knowledge 50 per cent. of the deaths need not occur. Sepsis was the greatest single cause. Some general practitioners still employed handywomen, and even nurses with the C.M.B. certificates had low ideals of asepsis. The asepsis of the general practitioner might be improved. Hæmorrhages could not be foreseen, but might be due to faulty conduct of labour. There should be a longer training of medical men with a view to more conservative midwifery. The relief of pain should receive attention, with a view to the avoidance of unnecessary operations. We had to consider how the general practitioner was to get experience if he did no normal cases in accordance with the new proposals. The training of the midwife should be improved and she should go through a pupilage. Handywomen must go. Sterilised outfits must be provided. The general practitioner's status would be improved if he were relieved of normal cases. A separate anæsthetist should be available and a consultant should be within call. *He favoured* the use of portable obstetric tables, and expressed his approval of the proposed midwife-doctor combination.

---

[1] See THE LANCET, 1929, i., 85.

Dr. H. L. MURRAY (Liverpool) also advocated hurrying slowly. We were awaiting the result of the national inquiry. He spoke in favour of antenatal treatment and the acquisition of a surgical intranatal sense. The expectant sense had been to some extent lost. In some cases the midwife insisted upon the doctor operating. Sepsis sometimes occurred in an unaccountable manner. Doctors should only employ midwives, but he thought the doctor should be present at normal confinements.

Dr. A. K. CHALMERS (Glasgow) pointed out the advantages of a hospital on the pavilion system for the separation of clean from suspected cases. Antenatal examination should be made a condition of admission to a maternity hospital.

Dr. JAMES YOUNG (Edinburgh) expressed his approval of the scheme of the Association for a national midwifery service. He thought the bogy of autogenous infection had been laid and that the statistics of the East End Maternity Hospital proved that it was negligible. He agreed with Dr. Chalmers as to the advantages of pavilion hospitals and that they must not have normal and abnormal cases in one building. Cæsarean cases were liable to be infected by contagion.

Dr. W. H. F. OXLEY (London) said that the East End Maternity Hospital had been going for 40 years. *It was staffed by midwives who called in the general* practitioners in the neighbourhood. Much of the credit for the good work was due to the head midwife, Miss Anderson, whose enthusiasm had inspired her staff. They had been doing antenatal work before Ballantyne began. Their cases were booked early and a forward look-out was kept. They had almost stamped out eclampsia, as among the last 10,000 confinements there had been only one slight fit in the present year. By intensive indoor treatment for albuminuria and by induction in cases which did not clear up under it, they were going a stage further than preventing eclampsia, and had reason to believe that they were diminishing the incidence of recurrent toxæmia and of chronic nephritis. Their treatment for placenta prævia included as little manipulation as possible. Early turning was not always needed. They had had no maternal death from placenta prævia among the last 14,000 cases. He thought antenatal treatment might be carried too far and become too much of a "stunt." Antenatal care was the preparation for the battle and the main thing was wise midwifery at labour. Their midwives did not use gloves but a proper strength (1 in 1000) of perchloride of mercury. Several pupil midwives examined each case but with carefully disinfected hands, and no harm was done thereby. The primipara had a threefold risk of puerperal pyrexia, and he had satisfied himself that this increased risk was due to trauma of the cervix. No doctor with an obstetric conscience could be forced by a midwife to interfere or to use forceps. If he had not developed *such a conscience it was the fault of his teaching.*

Dr. FARQUHAR MURRAY (Newcastle-upon-Tyne) thought the pupil midwives, who were practically handywomen, should not be too numerous. The hospital cases should be divided into clean, suspect, and dirty, and there would be no rise of temperature in the "clean" wards. Consulting obstetricians were needed for domiciliary cases. In nursing homes a separate nurse should be provided for each case. Special nurses should be provided for cases with early signs of sepsis through a domiciliary nursing service of a maternity hospital. He thought antenatal examinations should be conducted at a special centre and not in a doctor's surgery. He also spoke against the abuse of lysol.

Prof. J. HENDRY (Glasgow) agreed in deprecating the abuse of lysol and of vaginal examinations unnecessarily and badly done by midwives. Refresher courses for midwives were very necessary. A larger proportion of the doctors' cases were abnormal, because they included primiparæ, those who had had difficulty in previous labours, and those who desired to have chloroform and forceps. If the puerperal temperature was charted four-hourly much more pyrexia would be shown.

Dr. ARTHUR GILES (London) thought that general practitioners should attend normal labours. They must not, however, apply forceps to save their own time, and they should have a maternity hospital available for their patients. He believed in boiled gloves rather than perchloride.

Miss FRANCES IVENS (Liverpool) said that they needed properly educated midwives and must see that they were properly paid.

Prof. C. G. LOWRY (Belfast) said they need not wait for research but could apply the well recognised principles adopted at the East End Maternity Hospital. A rise of blood pressure always preceded albuminuria. There had been no case of eclampsia for nine years in his hospital. He disagreed with Mr. Bright Banister with regard to autogenous infection. Morphia and hyoscine were useful for avoiding interference in labour. It might also be good to use similar sedatives for the relatives! He was somewhat surprised at the number of vaginal examinations permissible for pupil midwives at the East End Hospital. He believed that ill-washed hands and unnecessary separation of the labia minora were frequent causes of bad results. Antenatal work should be done by those who would conduct the labour.

Dr. MIDDLETON MARTIN (Gloucester) thought the B.M.A. report a very practical contribution. In Gloucestershire the services of obstetric consultants were available, and there were maternity beds in each cottage hospital.

SECTION OF NEUROLOGY AND PSYCHOLOGICAL MEDICINE.

THE DIAGNOSIS OF FRONTAL TUMOURS.

Dr. JAMES COLLIER (London) opened the discussion. He said that from the very nature of the cerebral hemispheres the regional diagnosis of disease situated therein was often a matter of peculiar difficulty. In considering the possible signs of tumours within the frontal lobe, if we were to advance in knowledge, we must divest our minds of any idea of local function, mental or otherwise, peculiar to lesions of the prefrontal lobes. We must expect a varying clinical picture, and often one which was negative so far as *localising symptoms* were concerned. *It must be* borne in mind that there exists a great facility in compensation for local lesions within this region, so fully emphasised by Gowers 40 years ago, and also the disturbing effects that long-standing increase of intracranial pressure and hydrocephalus have upon the value of those signs which are used for localisation. We must strive to collect those signs which have been useful to us in the successful localisation of frontal lobe tumours. He might conveniently divide the signs which are used for the localisation of a tumour within the prefrontal lobes into five categories, thus: (1) the negative signs; (2) the contiguous signs; (3) the signs which have been deemed peculiar to, or especially marked in, prefrontal lesions; (4) the signs peculiar to lesions within the anterior fossa of the skull; and (5) the signs revealed by ventriculography.

Five Categories of Signs.

Negative Signs.—The negative signs were of especial importance, since tumours within the posterior fossa below the tentorium, and *those of the* occipital, parietal, central, and left temporal regions, except sometimes in their latest stages, gave unmistakable signs of their position. If no definite localising sign was present, therefore, it was often a matter of a prefrontal or a right temporal site.

Contiguous Signs.—The contiguous signs [illegible] those produced by the extension of some with the growth—pressure, œdema, or vascular disturbance—into the neighbouring ascending frontal gyrus and giving rise to motor weakness. Extension might occur into the insula of the left side, giving rise to interference with the execution of language, or into the paths converging to the anterior part of the corpus callosum and so producing motor apraxia. The motor weakness was usually seen first and most in the face, rarely in the arm, and almost never in the leg. It was perhaps the most important lateralising sign of a frontal tumour, but it did not distinguish a frontal tumour from a temporal tumour, which also frequently caused facial weakness as a contiguous sign. Difficulty in the exteriorisation of language was a certain lateralising sign of a left hemisphere lesion in a right-handed person, but it was also caused by tumours of the left insula and those of the anterior temporal region. It should be of the nature of a stammering defect or of a "pure aphasia" if due to a frontal lobe lesion. Pure executive apraxia appeared to be a certain sign of prefrontal involvement and to indicate a left-sided lesion. Presumably it pointed to a lesion extending deeply and far back in the upper two prefrontal convolutions.

Signs Peculiar to the Frontal Lobe.

Mental Symptoms.—Mental changes of a very variable order, from slight changes in the way of loss of reserve, childishness, and change of character, to severe disturbance such as megalomania, "witzelsucht," and dementia did result from tumours of the prefrontal region. Dr. Collier wished to ask whether the Section agreed with Cushing's very confident statement that mental changes were always much more conspicuous in left-sided lesions, for he, the speaker, was doubtful as to this point. Extensive lesions of the frontal lobe often existed without any obvious mental change. The explanation seemed to lie in the possibility of compensation, and whether the other frontal lobe was relatively intact as regards its callosal connexions, since bilateral frontal lesions always gave rise, both experimentally and clinically, to marked mental reduction. The point of importance was whether mental changes were of sufficiently higher incidence in prefrontal lesions, as compared with lesions of other regions of the brain, as to make them reliable symptoms when other localising symptoms were absent. The speaker wished specially to emphasise the early loss of memory and the mental reduction occurring in tumours of the splenium callosi, because it might be the key to the explanation of mental changes and their variability in cases of cerebral tumour. He suggested that in lesions of the prefrontal lobe mental changes were only conspicuous when the tumour extended deeply and cut the callosal and other transcortical paths.

Frontal tremors, more marked upon the homolateral side and sometimes confined to that side, like other signs at first described as indicating prefrontal lesions, had come to belong also to the temporal lobe.

The "*grasping and groping*" *reflex* was, as far as he, the speaker, knew, a certain sign of prefrontal location which had not yet been seen with lesions elsewhere. Dr. Gordon Holmes thought it was seen with very extensive frontal lesions, but the speaker disagreed with this opinion. Dr. M. Critchley associated it with lesions high up and far back in the prefrontal region.

Conjugate deviation of head and eyes, or of eyes alone, to the contralateral side, explained by the involvement of the frontal ocular area said to occupy Exner's region in the second frontal gyrus, had been repeatedly emphasised as of locating and lateralising value. It seemed to the speaker certain that every cortical region must of necessity be an origin for inducing conjugate deviation, considering the necessary association in life of conjugate deviation with every movement and sensation, and therefore conjugate deviation could not be in any way special to the prefrontal lobes; nor did he believe that there was any special region for this function. When present it was of certain lateralising value for tumours in any part of the hemisphere. It might be seen in the form of persistent deviation to the contralateral side, or of weakness and unwillingness in deviation to the homolateral side.

Loss or diminution of the trunk reflexes might be of great lateralising value and was said to be valuable in frontal location. But he held that it was much more characteristic of the temporal tumour.

Incontinence was sometimes very marked in frontal tumours, even when the mental aberration was inconspicuous. He thought he had seen it more often in temporal tumours.

Papillœdema was said by Mr. Leslie Paton to occur earlier and more severely with tumours of the hemisphere the farther forward these were situated. Recently Stopford had analysed another series of cases, and had come to the conclusion that the more posterior the situation the earlier and more intense the papillœdema. The speaker was inclined to agree with Stopford, although he did not think papillœdema was of any value either in localisation or lateralisation.

Lethargy of a deep but rousable kind had occurred many times in frontal tumour, and when existing without headache or papillœdema it had caused several cases to reach the post-mortem room with the label "lethargic encephalitis."

Fits of different kinds often occurred with frontal tumours. The convulsions he had seen had always commenced with conjugate deviation, which deviation had been a sure lateralising sign. Status epilepticus was an interesting frontal symptom. He had no knowledge of any other region of the brain in which a tumour had produced status epilepticus.

There remained for consideration certain phenomena, such as Meyer's reflex, Leri's reflex, and Hoffmann's reflex, which were said to be absent in prefrontal lesions, and Wessenberg's sign which was supposed to be found only when a prefrontal lesion was present.

Lesions of the Anterior Fossa.—Ventriculography.

Signs peculiar to lesions of the anterior fossa were those of pressure upon the olfactory tract, the optic nerve or chiasma, or upon the nerves and vessels passing through the sphenoidal fissure, and those of bony involvement. These were always certain localising and lateralising signs, but they only obtained with a hard tumour coming to the surface of the orbital lobe or with a growth of meninges or bone.

There remained the method of ventriculography, which in skilled hands had resulted in many brilliant successes in this and in other difficult regions of the brain.

Discussion.

Dr. W. J. ADIE (London) said that the "grasping reflex" had been of value in localising tumours of the opposite frontal lobe. The fully developed reflex was very striking but it also appeared in various incomplete forms; hence the term "grasping reflex" did not cover the entire phenomenon. In his opinion, it was not necessarily confined to extensive lesions. The fits seen in frontal lobe tumours might consist of some movement of the head, eyes, and trunk to the opposite side with simultaneous involvement of the limbs of the contralateral side. Such an attack, however, might also occur in temporal lobe tumours. A fit beginning with clonic movements of the eyes with deviation to the opposite side was of localising value in frontal lobe tumour; in fact, such movements might constitute the entire fit. Meyer's reflex was of great value, a unilateral exaggeration being a lateraliser to the opposite side and a localiser to the opposite frontal lobe. Dr. Adie considered that ventriculography was of great assistance in frontal lobe tumours.

Mr. GEOFFREY JEFFERSON (Manchester) considered that ventriculography could be well replaced by the method of "ventricular estimation." This consisted in the bilateral tapping of the ventricles by the occipital route, the withdrawal of cerebro-spinal fluid from each, and the comparison of the volume of the two fluids. He had not found the injection of dyes of great value. Mr. Jefferson then described certain cases of frontal lobe tumour which he had encountered, and illustrated his cases with admirable lantern slides.

Dr. L. J. J. MUSKENS (Amsterdam) said that he had also met with a case of frontal lobe tumour showing the sudden occurrence of status epilepticus without previous symptoms. Bruns had called attention to ataxia and vestibular symptoms in frontal lobe tumours. In 1917, he (the speaker) had pointed out that cats, after extensive right-sided lesion, and patients with right frontal tumours, tended to fall to the left. This observation was confirmed by Grossmann in 1919, who described six cases of frontal lesions from bullet wounds, all of whom fell to the contralateral side.

Dr. C. WORSTER-DROUGHT (London) considered that mental symptoms were more frequent in frontal lobe tumours than in those affecting other regions of the brain. In his experience the mental symptoms associated with right-sided lesions were slighter than those accompanying left-sided lesions; the former might consist of mental memory defects while the latter varied from euphoria to dementia. He agreed that involvement of the white matter of the brain was the important determining factor. Tremor he had found of no assistance, but the "grasping reflex" was a valuable sign when present; it was, however, often absent. Incontinence was a very frequent sign of frontal lobe tumours and might be the only symptom present or occur with only slight mental dullness. The absence of the epigastric and abdominal reflex on the homolateral side was also helpful. He had been impressed with the frequent absence of headache in cases of frontal tumour he had seen. Air ventriculography was of considerable assistance, but he had come to regard the procedure as somewhat risky in posteriorly situated tumours; he was, therefore, glad to hear Mr. Jefferson's opinion regarding the value of ventricular estimation.

Dr. J. GODWIN GREENFIELD (London) commented on the extraordinarily long history and the hardness of the tumour often met with in the astrocytoma type of frontal glioma. There was a greater tendency to degeneration and cyst formation in frontal lobe tumours; probably this resulted from some peculiarity of the blood-supply.

Dr. M. CRITCHLEY (London) stated that the phenomenon described by Adie and himself as "forced grasping and groping" had been originally reported by Janischewsky as the "réflexe de la préhension." The phenomenon was made up of several component parts. First, it comprised a slow and gentle flexion movement of the fingers on stimulation of the palm. The second phase consisted in a forceful and involuntary closure of the fingers when an attempt was made to withdraw an object from the patient's hand. The involuntary nature of the inability to relax the grasp was shown by the fact that a painful stimulus—e.g., a live electrode—still elicited an identical firm closure of the hand. After the object had been finally extracted from the patient's hand, the third phase of the phenomenon became manifest by a slow full extension of the fingers followed by a slight closure. In this way the patient's hand might again grasp the object that had just been withdrawn ("after-grasping"). In some cases a fourth phase was seen; during the examination of some other part, the patient's affected hand continually obtruded itself by clasping or groping towards the examiner's hands ("forced grasping"). It was now realised that the grasping phenomenon might affect regions other than the hand—e.g., the sole of the foot and the jaws. Although forced grasping and groping might be seen in various states of stupor and coma, and in some cases of diffuse cerebro-vascular disease, its presence in cerebral tumour usually indicated a frontal localisation. Although of great localising value, its importance as a lateralising sign required qualification. Cases have been noted in which the grasping phenomenon had occurred on the same side as the tumour, but in such instances there had been a severe degree of hemiplegia on the contralateral side. Presumably in such cases the tumours were large ones capable of producing bilateral signs.

Dr. F. R. FERGUSON (London) emphasised the importance of investigating all possible channels of information. Daily physical examination of the patient often revealed such variation in the physical signs that it was impossible to correlate them and localise the tumour. He instanced a case showing a marked right-sided "frontal tremor" but with other signs at one time indicating a left-sided frontal lesion and at others a right-sided. At autopsy a cholesteatoma was found exactly in the middle line at the posterior end of the corpus callosum. With regard to the localising value of the "grasp reflex," he mentioned a case with a right-sided grasp reflex in whom a left cerebellar tumour was found at autopsy. The cerebration and coöperation of this patient, however, were very poor and there was evidence of secondary hydrocephalus.

Mr. A. A. MCCONNELL (Dublin) considered that ventricular estimation was of more value in lateralising than in localising, and especially with frontal lobe tumours. A fallacy, however, was that frontal tumours might occlude the foramen of Monro and prevent the air reaching the opposite side.

SECTION OF OPHTHALMOLOGY.

Mr. J. GRAY CLEGG (Manchester) being in the chair, Mr. W. H. KIEP (Bradford) read a paper on a modification of

Lagrange's Operation for Glaucoma.

He referred to cases of late infection after trephining operations, and said it was obviously desirable that the membranous covering of any such fistula should be sufficiently thick to prevent entrance of organisms or their toxins. The operation he had adopted recently was a modification of Lagrange's; it had the merit of being easier to perform, and also of making a less extensive wound of the sclera. His own procedure was as follows: the conjunctiva and subconjunctival tissues were grasped with forceps 6 or 7 mm. above the limbus, and divided with scissors; Tenon's capsule was also divided, and a flap including these structures was reflected; a groove was cut in the sclera 2 to 2¼ mm. above the limbus, making a small furrow here; a keratome incision, of 3 to 4 mm., was made through this furrow; the keratome was withdrawn as quickly as possible in order to avoid any great loss of aqueous; the prolapsed iris was removed, securing a peripheral iridectomy; a small piece of the anterior lip of the incision was excised with scissors; the conjunctival flap was sutured with one stitch; it was practically always possible to get the iris back into position by manipulation without introducing any repositor into the anterior chamber; in this way further loss of aqueous was avoided. The drawback of the operation was that sometimes episcleral vessels of considerable size were cut. Otherwise he had found this operation no more difficult than Elliot's, and less difficult than Lagrange's. There was a minimum disturbance of intra-ocular structures. It was often possible to do it with little loss of aqueous. On an average, the anterior chamber regained its normal depth in from 48 to 72 hours after the operation. A fistulous orifice of 2 mm. width was obtained. There was ample protection from late infection. He had performed the operation successfully in one case where a large iridectomy had previously been done.

Mr. W. B. INGLIS POLLOCK (Glasgow) said that now for some years he had kept strictly to the Lagrange operation. Where the tension was much raised at the time of the operation he always did a posterior sclerotomy; the Lagrange operation could be done immediately after the posterior sclerotomy.

Mr. A. B. **Cridland** (Wolverhampton) said that after seeing Lagrange do his operation at Oxford in 1907 he had adopted it. There was no doubt that it was a difficult operation. An essential point was that you must "shave the base of the iris." Tension should first be brought down as low as 40. Any modification of Lagrange's operation that made it easier was to be welcomed. In 20 years he had never seen a case of late infection after it.

Mr. A. F. **MacCallan** (London) said that for the last five years he had never seen a case of late infection after trephining among his own cases or those of his colleagues. He had frequently seen superficial inflammation of the conjunctiva in trephined eyes without any infection of the deeper structures. Where hæmorrhage from episcleral vessels occurred he had found the application of a little dry wool moistened with adrenalin solution sufficient to arrest the bleeding.

Mr. H. H. **McNabb** (Manchester) mentioned a case of late infection which occurred 18 years after an Elliot's trephining operation.

Mr. E. E. **Maddox** (Bournemouth) described some modifications of Lagrange's technique which he had adopted. One of these consisted in slicing the crescent of sclera—i.e., making a series of transverse cuts in it with scissors.

The **Chairman** said he had adopted Elliot's trephine operation almost regularly, with slight modifications and had not seen late infection following it for a considerable time.

Mr. **Kiep**, in reply, said it was a matter of the utmost importance that the diaphragm of the eye should not be allowed to come forward. He had given up doing posterior sclerotomy, because he found that tension could be sufficiently reduced by medical means—bed, saline cathartics, eserine, dionine, and fomentations; and he had found Duke-Elder's method of reducing tension by intravenous injection of hypertonic saline solution very useful. In certain cases there was danger of hæmorrhage from posterior sclerotomy. As to the difficulty of Lagrange's operation, that was a matter of personal opinion. There were certainly some expert operators who found it presented difficulty. In his experience it was far easier to place the incision accurately with a keratome than with a Graefe knife. His own method involved only the minimum of fuss and hæmorrhage. He would not advise operation in cases of very high tension especially if it had been present for some days, particularly in old people with degenerated arteries. In such cases he would first reduce tension by Duke-Elder's method, and operate about a week after.

Mr. **Cridland** (Wolverhampton) then read a paper on

Minor Injuries of the Eye in Industry.

These injuries, he said, ranked high in the list of causes of blindness. Not less than 100 cases of total blindness per annum were due to this cause in the United States of America. Eye injuries, according to Prof. Collis, constituted 5 per cent. of all accidents in industry reported by certifying surgeons. Estimates of the proportion of cases of blindness due to accidents varied from 7·2 per cent. in Scotland to 13·5 per cent. in U.S.A. In this paper his object was rather to direct attention to the minor injuries of the eye, and especially to their economic effect, as well as the steps necessary for their prevention. At his own hospital at Wolverhampton 6880 cases of accident to the eye had been dealt with in 1928, as compared with 6040 other new cases due to disease or requiring refraction testing. In the last 20 years the proportion of accidents to other cases at this eye hospital had increased from 39 per cent. to 53 per cent. The vast majority of these were, of course, minor injuries, especially foreign bodies, mostly small, that did not penetrate the eye. In 1928 the giant magnet was only used in 12 cases. From the point of view of occupation these patients might be divided into three groups: (*a*) occupations involving exposure to small flying particles—e.g., from grindstones or emery wheels, 51 per cent.; (*b*) occupations involving exposure to chips of metal, 26 per cent.; (c) miscellaneous—miners, roadworkers, painters, plasterers, &c., 23 per cent. Injuries varied in severity from a simple foreign body on the cornea to burns of the eyelids, or lime in the eye. Foreign bodies on the cornea furnished no less than 90 per cent. of the cases. Abrasions of the cornea provided 5 per cent., and there were 5 per cent. of miscellaneous injuries including burns, contusions, &c. In regard to protection, the following facts were elicited, based on information in 406 cases:—

1. Protection was not available in 70 per cent.
2. Protection was admitted to have been available, but not used, in 19 per cent.
3. Protection had been made use of, but had not prevented the injury in 11 per cent.

As regards time lost from work owing to the accident a series of 426 cases were divided into three groups:—

1. Those who lost from 1 to 2 hours, comprising those presumed able to return to work at once—371 cases.
2. Those who lost from 2 to 8 hours—48 cases.
3. Those who lost from 8 to 24 hours—7 cases.

The above figures probably underestimated the time actually lost. All things considered, it would be within the mark to say that on the average three of these minor eye injuries meant that the employer lost a full day's work. From the point of view both of employer and employed it was a matter of urgency to prevent such injuries. There were two obvious ways of doing this: (1) to ensure that the flying particle did not reach the eye, and (2) better still, to eliminate the flying particle altogether. On these two essentials the three main principles of prevention were based: (1) mechanical guarding, (2) education of workmen and foremen, and (3) engineering revision. Under the first heading came goggles of various forms, machine guards and shields, face-masks, helmets, or hoods. Goggles of the right kind properly worn and kept in order were the most important of these. The difficulty lay in producing ideal goggles at a reasonable price. For workers at emery wheels, a cheap but very effective form of protection against light particles was a piece of silk gauze worn as a veil over the eyes. These could be supplied at 2*s.* a dozen. Workmen should be made to realise the risk they ran, and how best to avoid the danger. In the third method of prevention, engineering revision, lay the hope of the future; it sought to eliminate the underlying cause, not merely to cover up the danger points. This end might be attained by the changing of a process of manufacture, by the redesigning of a machine or tool, or rearrangement of the physical equipment of a plant, or changing of the method of work. The introduction of the automatic machine was one instance. In America some success had followed the employment of "safety engineers"—men whose duty it was to concentrate on engineering revision, and also to give special attention to the education of the workmen by propaganda and various ingenious and telling methods. For instance, in one workshop an enucleated eye was hung up in a bottle in a conspicuous place as a warning. The psychology of the workman must be considered. In this country, perhaps, education in this matter was more difficult owing to the spirit of indifference to danger, coupled perhaps with ignorance of the risks run. The subject was a very wide one, and each type of occupation called for special study and investigation. At present the economic loss from this cause was not realised.

Mr. N. **Bishop Harman** (London) mentioned that it was possible for flying particles to pass between the goggles and the face, and strike the eye—e.g., in overhead work.

Mr. T. **Aubrey Jones** (Stoke-on-Trent) spoke of the deeply rooted opinion among miners that glasses of any kind are an absolute danger when working down in a coal mine. He had seen very few injuries caused by wearing glasses. Many injuries in the mines would be prevented by wearing ordinary glasses. He thought Mr. Cridland's estimate of time lost by these injuries was too low.

Mr. H. L. G. LEASK (Glasgow) also referred to the miner's strong prejudice against glasses.

Mr. TUDOR THOMAS (Cardiff) said that in mines clouding of the glasses by dust and by sweat, especially in hot mines, might increase the liability to accident.

Mr. H. R. BICKERTON (Liverpool) said that each occupation required its own form of protection. It was useless to try to educate the workmen. They must preach to the employers and insurance companies.

Mr. CRIDLAND, in reply, said he had only touched the fringe of the subject. Ricochet would explain many of the cases where a flying particle got behind the workman's goggles. Side-pieces to the protective goggles had the objection that they were likely to cause sweating and dimming of the glass. In regard to miners, he did not think they would be induced to wear glasses, nor did he think it feasible that they should. All emery wheels ought to be fitted with proper guards. He wished to emphasise another aspect of these injuries—namely, the unnecessary burden thrown on the hospitals by the large number of these preventable accidents. In his experience insurance companies were very hard to educate in this matter.

Dr. T. L. DE COURCY (Liverpool) read a paper on the

Significance of Vitreous Opacities.

After referring to the work of Miss Ida Mann and Mr. Duke-Elder, he pointed out that any alteration in the metabolism might affect the vitreous. Many focal infections might show no other result in the eye but vitreous opacities—e.g., the dust-like opacities in the vitreous in syphilis. By careful ophthalmoscopic examination in three series of 100 consecutive patients he had found vitreous opacities in about 37 per cent. Few of these patients complained of any symptoms due to them. They were comparatively rare in children. Early cataract was frequently associated—and possibly the causation was the same.

Mr. MACCALLAN said that in a series of 100 cases, all of whom had normal vision with correction, he found vitreous opacities in a much greater percentage than Dr. de Courcy by examination with the slit lamp. In children with enlarged and septic tonsils the vitreous was never clear.

Mr. J. JAMESON EVANS (Birmingham) read a paper on

Blindness in Old Age,

based on some 700 cases examined with reference to their inability "to perform work for which eyesight is essential." This was the Government's definition of blindness. This series included 205 cases of cataract—of which 37 per cent. were certified as operable. There were 43 cases of retinitis pigmentosa. Among the optic atrophy cases 13 per cent. were due to syphilis, 10 per cent. were of cerebral origin, and the rest of unknown origin. There were nine cases due to ophthalmia neonatorum, and nine cases due to sympathetic disease. In myopic cases blindness was due chiefly to choroido-retinal degeneration.

Mr. HARMAN was surprised to hear that cataract headed the list as a cause of blindness in old age in these cases. His impression was that degenerative or inflammatory changes at the macula were the chief cause. 6/60 had been suggested as a definite standard for these cases. He was strongly opposed to any such stringent and rigid definition of blindness for certification for Government regulations. In each case the decision should rest with the ophthalmic surgeon. It must be remembered that they were not asked to certify that the patient could do his own work, but that he could not see to do *any* work for which eyesight was essential. Many domestic workers who had never worked outside their own families were now applying for pensions under these regulations.

Reviews and Notices of Books.

A SYSTEM OF BACTERIOLOGY IN RELATION TO MEDICINE.

By various authors. Vol. III., pp. 413. By W. BULLOCH, P. FILDES, A. T. GLENNY, H. HENRY, R. T. HEWLETT, R. A. O'BRIEN, S. G. PAINE, G. F. PETRIE, MURIEL ROBERTSON, R. ST. JOHN-BROOKS, W. G. SAVAGE, A. C. THAYSEN, H. G. THORNTON, R. L. VOLLUM. London: H.M. Stationery Office. In 9 volumes. £8 8s. or £1 1s. per volume.

THE Medical Research Council have sponsored many notable contributions to scientific medical literature since the publication in 1915 of the first number in the special report series at the modest price of 3*d.* The familiar green books are to be found in laboratories and libraries all over the world, and include records of investigations which would never have been undertaken except under the auspices of the Council, and could scarcely have been published in any other form. The most ambitious literary project of the Council is the System of Bacteriology of which the first volume (Vol. III.) has just been issued. The system, which is to be published in nine volumes, is the work of some 100 British bacteriologists. The general editorship is in the hands of Dr. Paul Fildes and Prof. J. C. G. Ledingham, and Dr. Fildes has been assisted in the heavy work of organisation and preparation by Dr. Edgar Schuster. Probably few people are in a position to appreciate to the full the amount of work entailed in the editing of a complicated publication of this nature; it must have been immense, and the editors are to be congratulated on the manner in which they have performed their task.

There will be no two opinions as to the need for such a publication as this. There are numerous excellent text-books of medical bacteriology in the English language, but there is no really comprehensive work which takes cognisance of the whole range of bacteriology in its relation to medicine. As Lord Balfour points out in his general preface, the subject of bacteriology is so vast and covers so many fields of human activity that it is impossible for any one man to keep in touch with all its developments. Hitherto it has been difficult for any worker in one field to make himself acquainted with the progress being made in another; the medical bacteriologist, for example, may be profoundly ignorant of the important work being done by his veterinary colleagues or by the agricultural bacteriologist; and even in medical bacteriology specialisation has advanced to such a degree as often to isolate the pioneer. But with this system at his elbow it will be possible for everyone interested in the subject to form some general picture of the whole; and should he desire to go deeper into the matter he will find guidance to the original sources he should consult. Moreover, in a survey of this kind the gaps in our knowledge are likely to become apparent.

Vol. III., the first of the series to be published, deals with Economic Bacteriology, Plague, Anaerobes, and Food Poisoning. In Chapter I. A. C. Thaysen deals with the economic aspects of bacteriology, including baking, retting, decomposition of cellulose, the fermentation of indigo, coffee bean, tobacco, starch, and sugar, the decomposition of nitrogen compounds, and the bacteriological aspects of the formation of minerals, including coal. In Chapter II., H. Henry discusses the bacteriology of water and the examination of water-supplies. Chapter III., by R. L. Vollum, is devoted to the bacteriological aspects of the dairy industry, and in Chapter IV. W. G. Savage deals with other foodstuffs. Soil bacteria are considered in Chapter V. by H. G. Thornton; Chapter VI., Bacterial Diseases of Insects, is in the hands of R. St. John-Brooks, and in Chapter VII., S. G. Paine treats of the bacterial diseases of plants. These seven chapters occupy about a third of the volume; their subject matter is condensed and, indeed, treated somewhat superficially. Nevertheless they form an interesting and valuable contribution; the authors have shown considerable judgment in determining what to leave out, and the medical bacteriologist will be grateful for this résumé of a subject with which he is rarely familiar. In Chapter VIII., which deals with *Bacillus pestis*, we are on better-known ground. This section is contributed by G. F. Petrie and is preceded by a short historical note by W. Bulloch. After discussing the general bacteriology of *B. pestis*, the author turns to the problems of plague immunity, and then deals with the transmission of the infection by the rat-flea, natural plague in rodents and other animals, and bubonic and pneumonic plague in man. Dr. Petrie has written a very complete and satisfying account of his subject, but it is perhaps a pity that his contribution should have been separated from that dealing with the Pasteurella group, which is to appear in Vol. IV.

Miss Muriel Robertson deals in the next section with the organisms associated with gas gangrene, and as we should expect, gives an admirably clear and lucid summary of this very difficult subject. In a brief historical summary she shows how the complexities which have surrounded this group of organisms have arisen, and then proceeds to describe the more important and definite varieties. Pathogenic action, resistance, and immunity are next discussed, and the chapter closes with a section by R. A. O'Brien on the preparation and testing of toxins and antitoxins, and prophylactic mixtures. A serious omission in this article is the absence of illustrations, and this applies to the rest of the volume, excepting the chapter on soil bacteria which contains 13 charts and figures. Readers of the Council's special report series Nos. 12 and 39, which dealt with the anaerobic organisms, will recall the really beautiful illustrations which enriched these publications and will regret that they are not reproduced here. In Chapter X. Dr. Paul Fildes gives an admirable account of *Bacillus tetani*. Here again the article is conceived on the broadest lines, and much attention is devoted to the pathological effects of the organism, its portals of entry, the mechanism of infection and intoxication, and immunity. The organisms resembling *B. tetani* are briefly discussed, and R. A. O'Brien and A. T. Glenny contribute an account of the production of antitoxin for therapeutic purposes. The chapter is introduced by an historical note by W. Bulloch. Chapter XI., on *Bacillus botulinus*, is by R. Tanner Hewlett, with sections by W. Bulloch and R. A. O'Brien, and the volume ends with a short chapter by W. G. Savage on Bacterial Food Poisoning.

The general subject index is to appear in Vol. IX., and there is no index in this volume, but the table of contents is very full and complete. We have nothing but praise for the general format of the volume. It is dignified and workmanlike, and in every way worthy of what will be a notable publication.

LETTERS FROM ROME.

Letters from Rome on Certain Discoveries Connected with Malaria. By T. EDMONSTON CHARLES, M.D., Q.H.P. With Addenda, consisting of an article by S. CALANDRUCCIO, letters from ROBERT KOCH and A. LAVERAN, and a statement by Lord LISTER. Edited, with Preface and Remarks, by Sir RONALD ROSS, K.C.B., K.C.M.G., F.R.S. London: Ross Institute and Hospital for Tropical Diseases, Putney Heath. 1929. Printed by Harrison and Sons, Ltd. Pp. 78.

DURING the time when Sir Ronald Ross was investigating the connexion between mosquitoes and malaria, certain Italian observers, of whom Prof. Grassi was the leader, were also engaged in the experimental study of the problem. The priority of Sir Ronald Ross's discovery of the zygotes is no [illegible] notubt, but in order that it shall be finally [illegible] was o[illegible] has now published certain letters of [illegible]iew of occu[illegible] at the time by Dr. T. Edmonston Charles. The letters cover a period from Nov. 4th, 1898, to Jan. 14th, 1899, and are fully annotated by Sir Ronald Ross, who has also supplied explanatory postscripts. Other confirmatory documents are included in the book, and a list of the published literature immediately connected with the subject is set out in chronological order. Letters from Robert Koch and A. Laveran expressing disapproval of the attitude of the Italian school are also printed together with a statement, quoted from the *Times*, made by Lord Lister. Lister's reminder of the candour, openness of mind, and readiness to recognise the work of others shown by Ross is worth recording for the benefit of future generations, who may see only Ross's own writings, which will survive, but not the attacks to which they provide adequate answers.

THE TOXÆMIAS OF PREGNANCY.

By H. J. STANDER, Associate Professor of Obstetrics, Johns Hopkins University Medical School. London: Baillière, Tindall and Cox. 1929. Pp. 161. 13*s*. 6*d*.

THIS book, forming Volume XV. of the Medical Monograph series, is intended, as are its companion volumes, to provide teachers, clinicians, and laboratory workers with a critical digest of recent views in convenient and readable form. The first 15 pages are occupied with a description of the metabolic and other changes occurring in normal pregnancy, and the remainder of the book with a very full consideration of the toxæmias of pregnancy, amongst which ante-partum hæmorrhage is not included. A good discussion of the theories of causation of hyperemesis and of the chemical changes in the blood and urine is included. The author believes that all cases are based on an underlying toxæmia, though in some women the toxæmia may be so obscured by a predominating neurosis that one is almost entitled to make a diagnosis of neurotic vomiting; he has little doubt "that the changed metabolism accompanying pregnancy, which may so easily become perverted, as shown by the tendency towards acetonuria . . . is the underlying cause of all cases of vomiting of pregnancy." The best method so far available to restore the patient to a normal metabolism is said to be insulin and glucose. The value of complete isolation of the patient and of suggestion in these cases is stressed, and also the need for combating dehydration, if necessary by subcutaneous injection. The author proceeds to deal with the "low reserve kidney," a term first introduced by Stander and Peckham. This condition is ascribed to toxæmia, and is associated with a mild degree of hypertension, albuminuria, and œdema; it is difficult to see in what respect it differs from a mild form of the "pregnancy kidney" familiar to us all. The "low reserve kidney" invariably clears up after delivery; it may recur in successive pregnancies, but never in a more severe form or at an earlier period of the pregnancy—in short, permanent kidney damage is never sustained. Prof. Stander gives a helpful and comprehensive review of the various tests of kidney function. He believes that the urea-concentration test, as modified by Rabinowitch, will prove the most useful test in diagnosis and prognosis. He strongly advocates the termination of pregnancy in all cases complicated by chronic nephritis, unless decided and rapid improvement follows rest in bed with restricted low protein diet and plenty of fluid. If there is much œdema a salt-free diet is advocated. Forty pages are devoted to a discussion of the causation of eclampsia. Prof. Stander comments on the increased lactic acid in the blood in eclampsia, and considers the phenomenon of decreased or deficient oxidation "the most fundamental finding yet discovered in eclampsia." In treatment he advocates conservative tactics and describes the modified Stroganoff method now in use at Johns Hopkins. Venesection finds no favour, since high blood pressure may be a protective mechanism leading to increased elimination; but, if used at all, large quantities should be withdrawn (750–1000 c.cm.).

with the object of removing toxins. Radical interference should be practised, preferably under spinal or local anæsthesia, only if, in spite of conservative treatment, the patient becomes progressively worse. It is disappointing to find no reference to the remote prognosis of albuminuria and eclampsia; this should have attention in future editions.

The volume is a concise and reliable statement of the present position of our knowledge of the toxæmias of pregnancy, and deserves to be widely read. A bibliography containing over 700 references to literature is appended.

THE EXPECTANT MOTHER AND HER BABY.

By BODH RAJ CHOPRA, M.B., Ch.B. Edin. Edinburgh: W. Green and Son, Ltd. 1929. Pp. 148. 8s. 6d.

THIS book is apparently intended for circulation in India. It is divided into two parts which are unequal both in length and in quality. The second and larger part on the care of the child is so good that the defects of the brief section into which advice to the expectant mother is compressed are regrettable. Examples of assertions to which we take exception may be quoted. Under the heading "Mental Discipline," it is stated that "the mind of the parents, both generally and at the time of procreation, and also the subjects constantly heard by the mother during the period of pregnancy, influence the form, the attributes, and even the complexion of the child." We are told that the custom "prevalent among European nations" of spending the honeymoon in "places of natural charm" is designed to make the mother bring forth an "ideal offspring." The method of preparation of the nipples by hardening with eau-de-Cologne and spirits finds little favour amongst obstetricians in this country. Only 24 pages of the book are devoted to advice to the expectant mother regarding the care of her own health, and no counsel is given regarding the importance of such warning symptoms as hæmorrhage in late pregnancy, headache, visual disturbances, scanty urine, or œdema. These are serious omissions. Fourteen pages are devoted to "directions for the attendant" on the conduct of labour and care of the newly born child. This section is elementary, and is evidently intended for women with little training; for these it would be useful enough, although we deprecate the practice, in this country happily becoming extinct, of putting the forefinger into the baby's mouth in order to remove mucus. In the instructions regarding the care of the baby's eyes no mention is made of the prophylactic use of silver nitrate solution. The attendant is advised to bathe the eyes with boracic solution, and when inflammation sets in to send for a doctor.

The greater part of the book is given up to the feeding of the infant, artificial feeding, hygiene of infancy, the normal growth and development of the baby, ailments, and infectious diseases, with a final chapter on the mentally deficient child. This part is exceedingly well written. The advice given is sound and is expressed in concise and simple language. Much of it reflects the teaching of the late John Thomson, of Edinburgh, to whom the author expresses his indebtedness. If in future editions the first part of the book can be brought to the level of the last eight chapters, it should become a popular text-book.

GASES AND LIQUIDS.

By J. S. HALDANE, C.H., M.D., F.R.S., Fellow of New College, Oxford; Director of the Mining Research Laboratory, and Hon. Professor, University of Birmingham. London and Edinburgh: Oliver and Boyd. Pp. 331. 18s.

THIS contribution to molecular physics takes the reader into such various fields as the dynamical theory of gases and heat, gaseous diffusion, osmosis, the depression of freezing points of solutions, the internal pressure of liquids, and finally the steam engine and some other heat engines. The book is stimulating since it is the result of individual thought on the part of the author, who is vigorous in denouncing what he holds to be fallacious teaching in the realm of thermodynamics. It is possible that he is unfair to pioneers of the stamp of Clausius, Kelvin, and Clerk Maxwell. Their generalisations may well have been made with the mental reservation that their theories still left many phenomena unexplained.

A TEXT-BOOK OF PHARMACOLOGY AND THERAPEUTICS.

By HUGH ALISTER MCGUIGAN, Ph.D., M.D., Professor of Pharmacology and Therapeutics, University of Illinois College of Medicine. London and Philadelphia: W. B. Saunders Company, Ltd. Pp. 660. 28s.

IF we are to judge from the quotations in the preface of this book Prof. McGuigan has a profound belief in the necessity of the closest alliance between theory and practice, and with that in view he has attempted to correlate the facts of physiology, biochemistry, and pharmacology with clinical application. He has achieved only a fair measure of success, partly perhaps because he has undertaken a difficult and complex task; but mainly, we think, because of the unsystematic arrangement he has adopted in dealing with special pharmacology. The book breaks no new ground. It follows the general plan of most of the standard works on pharmacology and therapeutics, each drug being taken seriatim, its chemical characteristics described, its pharmacological action discussed, and its therapeutic uses mentioned. The information offered, particularly on the pharmacological aspect, is extensive, accurate, and up to date, and the introduction deals in a specially interesting way with the modes of action and the absorption of drugs. A number of excellent diagrams which have been reprinted from the author's well-known work on experimental pharmacology illustrate the seat and nature of action of important drugs. The book contains also a chapter on the pharmacological action of immune serums and notes on the pharmacopœial preparations and prescription writing. It fails only when it is judged on the standard of the author's own high ideals for such a text-book, and is at least as useful an adjunct to clinical work as are most other clear accounts of modern pharmacology.

PHYSIOTHERAPY.

Theory and Clinical Application. Second edition. By HARRY EATON STEWART, M.D., Director of the New Haven School of Physiotherapy. London: Humphrey Milford, Oxford University Press. 1929. Pp. 395. 34s.

THIS second edition of Dr. Stewart's book has the same general arrangement as its predecessor. It is divided into two main parts. In the first the author describes the nature, mode of action, and properties of the physical agents used in the treatment of disease. Electrotherapy, phototherapy, ultra-violet ray therapy, hydrotherapy, massage, remedial exercises, and muscle-training are considered in turn. The second part deals with the clinical aspects of physiotherapy. Dr. Stewart recommends the form or forms of physical treatment which are likely to produce benefit in different diseases, and describes the technique of their administration. The book concludes with suggestions for the treatment of miscellaneous maladies, postural defects, and some foot disabilities. The author deals with all forms of physiotherapy (excepting X rays), and as he has had considerable experience he is able to give impartial advice in the selection of appropriate methods. The perplexity of the beginner who has studied different branches of physiotherapy in separate books, and finds overlapping of the therapeutic fields mapped out for each kind of treatment, will thus be solved, and for this reason alone the book can be recommended. But there are other good grounds for reading it. For example, Dr. Stewart is a protagonist of the treatment of lobar pneumonia by diathermy, and has here summarised his experience in a convincing way.

In the pages dealing with high-frequency currents Dr. Stewart points out that there is risk in subjecting the brain to diathermy. Some patients have suddenly lost consciousness during the treatment without showing any premonitory symptoms. In the chapter on Exercise he speaks with authority of the value of athletics for the adolescent female, for he has been athletic director to secondary school girls and instructor in a normal school of physical education, and, later, physician and head coach to the American team at the first international track and field contest for women held in Paris in 1922. In his view the drastic change that has taken place in the physical life of the American girl during the last two decades has led to no harm and to much good, though he stresses the need for care in preliminary medical examinations and for competent supervision. He states that carefully followed up records of graduates of normal schools of physical training have shown menstrual and maternal histories better than those of the average woman.

Dr. Stewart's book can be confidently recommended to the student and practitioner of physiotherapy. It furnishes the reader with the American point of view of the subject, and at the same time gives adequate reference and credit to the work of European investigators.

THE TREATMENT OF CATARACT AND SOME OTHER COMMON OCULAR AFFECTIONS.

By Lieut.-Colonel HENRY SMITH, C.I.E., B.A., M.D., M.Ch., Indian Medical Service (retired) (London). With the collaboration of Lieut.-Colonel A. E. J. LISTER, F.R.C.S., I.M.S. (retired) (London), Dr. ARNOLD KNAPP (New York), and Dr. J. RUSSELL SMITH (London). Illustrations by Dr. DERRICK T. VAIL, University of Cincinnatti, and Dr. J. RUSSELL SMITH (London). Calcutta: Butterworth and Co. (India), Ltd. Pp. 287. 15*s.* 6*d.*

IN 1910 Lieut.-Colonel Henry Smith wrote a book on the treatment of cataract published by Messrs. Thacker, Spink and Co. We welcomed its appearance, since it enabled us to obtain a clear conception of the author's attitude to the classical method of extraction of cataract, as well as a detailed account of the intracapsular method which has been so successful in his hands and in those of his disciples. Colonel Smith has now entirely rewritten the monograph, which in its present form is published by Messrs. Butterworth and Co. Those ophthalmologists who wish to study the latest improvements devised by the author for his operation will find them described and clearly illustrated by numerous diagrams on pages 102 to 123. Colonel Smith believes that the new technique will put his original method into disuse. He claims, moreover, that the obstacle which in the past "quite rightly prevented the profession in the West from adopting it—that with its more limited opportunities for acquiring the necessary technical skill there was no method at its disposal from which it could hope to obtain success"—is now removed. The operation recommended has been reduced to a simplicity which, its originator believes, should enable it to be performed in relatively unskilled hands, not merely with a lower incidence of loss of vitreous than the capsulotomy operation when in the latter an adequate attempt is made to clear the eye of cortical lens matter, but even without that rupture of the hyaloid membrane which is a result of interfering with an after-cataract.

An interesting note on the historical aspect of the surgical treatment of cataract is included in the book, with a short account of lens couching as performed by the "rawals," a hereditary caste which originally sprang from a group of villages in the Punjab. A final chapter is devoted to the treatment of glaucoma and some other common ocular affections, and contains useful hints.

The FRENCH MEDICAL ANNUAL, *L'Année Médicale Pratique* (Paris: René Lépine. 1929. Pp. 621), appearing for its eighth year under the skilful editorship of Dr. Camille Lian, is well up to standard. This volume contains an adequate summary of the principal contributions to French medicine during the past year, and gives an interesting idea of the trend of continental opinion. The growing importance of all forms of radiotherapy is obvious in many sections; an able description is given by the editor of the treatment of angina pectoris by this means. The treatment of various forms of anæmia by liver diet or extract receives due notice, and an interesting account of the epidemic of dengue which raged in Athens during the summer of 1928 is included.

JOURNALS.

BRITISH JOURNAL OF CHILDREN'S DISEASES. Vol. XXVI. July-September.—Dr. Fergus R. Ferguson and Dr. Macdonald Critchley contribute the first part of a paper, entitled A Clinical Study of Congenital Neurosyphilis, based on the records of cases at the National Hospital, Queen-square, during the last decade. The cases consisted of congenital G.P.I., congenital tabo-paresis, congenital tabes, and a heterogeneous group which included epileptiform convulsions, mental defect, meningitis, hydrocephalus, cranial nerve palsies, paralysis of the extremities, and examples of the so-called nervous child.—In a paper on the Nervous Complications of Whooping-cough, Dr. W. Gordon Sears reviews the literature and records three personal cases. He suggests the following classification: 1 (*a*) Convulsions and coma; (*b*) spasm of the glottis. 2. Paralysis: (*a*) cerebral type; (*b*) spinal type. 3. Meningeal syndrome and meningo-encephalitis. 4. Peripheral neuritis. 5. Mental and other nervous changes, including hysteria, hypochondria, melancholia, epilepsy, and dementia. Sears comes to the conclusion that the primary cause in all these types of nervous complications is toxic, and that a meningo-encephalitis is the primary lesion.—Dr. N. Gray Hill contributes a paper on Herpes and Varicella based on the study of cases of these two diseases at Queen Mary's Hospital for Children, Carshalton, since May, 1926. His conclusions are as follows: 1. Herpes zoster is an infectious disease, and persons suffering from it should be isolated. 2. Herpes zoster may give rise to either varicella or herpes in susceptible persons. 3. The cutaneous lesions of herpes zoster and varicella are very similar. Investigation of the spinal cord should be made to determine whether there is a similarity in the cord lesions of the two diseases. 4. An attack of varicella confers no immunity against herpes zoster. 5. Further investigation is required to determine if an attack of herpes zoster will confer immunity against varicella.—In a paper entitled Tracheotomy and Tuberculosis Dr. J. D. Rolleston shows from a review of the literature and his personal experience that there is no justification for Landouzy's statement that children who have undergone tracheotomy for laryngeal diphtheria are specially susceptible to pulmonary tuberculosis and that very few reach adult life. On the other hand, hoarseness and liability to bronchitis are not infrequent sequelæ of tracheotomy.—In a note on the Nature of the Milroy-Nonne Disease, Dr. F. Parkes Weber shows that Nonne's cases of congenital and hereditary elephantiasis, published in 1891, were of the same nature as the cases of hereditary œdema reported by Milroy in 1892. Although no anatomical or histological study has yet been made, the cause of the condition is probably a lymphatic obstruction of some kind due to an antenatal or postnatal developmental abnormality of lymphatics and connective tissue. In support of this view is the occasional association with the œdema of other congenital defects such as spina bifida occulta, dental abnormalities, and congenital heart disease.—The abstracts from current literature are devoted to nervous and mental diseases.

THE LANCET.

LONDON: SATURDAY, SEPTEMBER 28, 1929.

THE TRAINING OF MIDWIVES.

The report of the Departmental Committee appointed by the Ministry of Health in May of last year to consider the working of the Midwives Acts, 1902–26, will disappoint those who are more immediately concerned with the training of midwives for their practical duties than with the administrative control of their profession, or the adjustment of their place in a national maternity scheme. Less than a quarter of the report is, indeed, concerned with the training of midwives. The study of "conditions under which midwives are employed," which was included in the terms of reference, has proved so attractive that the Committee have made it the occasion for promulgating a scheme for a national maternity service, linked up with the National Health Insurance Acts. The scheme thus launched under official sanction bears a striking resemblance to that recently accepted by the representative meeting of the British Medical Association. We have already commented favourably on that scheme, and need now only record our fear that its proposals will attract public attention to the exclusion of the contributions which this report does in fact make to the difficult and complicated subject of the training of our midwives. This would be the more unfortunate, since the national scheme has allotted to practising midwives a rôle so important and so extensive that the question of their training and education becomes a matter of first importance to the State. The public will expect satisfactory assurances that the average midwife is really competent to discharge the grave responsibilities which will be placed upon her; the report assumes that nine-tenths of the half-million mothers who will come into the national scheme will be attended by midwives alone. The Committee do not express dissatisfaction with the present training of our midwives, or with the general standard of knowledge and efficiency which they attain on certification, though they do point out certain directions in which training could be improved. These are excellent as far as they go, and include (1) an entrance examination in reading, writing, and arithmetic, subjects in which it appears that a considerable proportion of our midwives are rather shaky; (2) a clinical examination before certification; (3) a post-certificate period of three months "hospital" experience, during which personal attendance on "at least five cases"—surely a very small number—is required: (3) post-graduate or "refresher" courses, at intervals, without expense to the practising midwife.

These changes, if they are carried out, will make no fundamental alteration in our present system of training. Under this system we take large numbers of almost uneducated women, who have had no training in general nursing, who are ignorant of the elementary facts of anatomy and physiology, and we attempt, in 12 months, to turn them into efficient midwives, to whose care the lives of our mothers may be entrusted. Where the raw material is sufficiently good, and where an intensive training can be given under the most skilled teachers, the task may be feasible; but only when clinical material is abundant. Unfortunately, however, the amount of clinical material available for teaching is woefully deficient, and in some of the largest institutions medical students and pupil midwives compete with one another for cases. Moreover, a considerable proportion of the cases available for pupil midwives are absorbed by those who do not intend to practise as midwives, but take the training because it is an essential qualification for the post of health visitor. The irony of the situation from the point of view of the midwife is that her work is liable to supervision by these very health visitors, who have never practised midwifery, and have never gained the experience which, under our present system, can only be acquired after training. The Committee suggest no drastic alteration of this system, which they propose to leave practically as it stands. They must be aware that it compares unfavourably with the practice of other European countries which utilise the services of midwives. There are 103 independent "schools" for the training of midwives in England and Wales, varying greatly in size, while nothing approaching a common standard of organisation or efficiency exists among them. Some midwives are accordingly well trained, others badly. No solution is offered in the report to the problem of the supply of clinical material for the pupil midwife. In fact, the needs of the medical student are recognised to be so urgent that the Committee conclude that the training of pupil midwives in hospitals attached to medical schools must suffer some restrictions; they add "students in a medical school area should have preference in the apportionment of material, and . . . . pupil midwives in that area should be allowed to make use of such material only in so far as it is in excess of the needs of medical students." If this recommendation is adopted, as on other grounds we trust it will be, the opportunities for pupil midwives to handle cases in hospitals attached to medical schools will greatly diminish. The fact that "the midwife occupies an exceptionally responsible position . . . . compared with women employed in allied branches of nursing" is admitted by the Committee, who, nevertheless, believe that the time has not yet come either to increase the length of the midwife's special training or to require a preliminary training or experience in general nursing.

It is clear that the opportunities and emoluments at present offered by the profession are not likely to attract highly educated women to its ranks, or to encourage others to undergo a long and arduous period of training to fit themselves for its practice. Moreover, fundamental alterations in an established system cannot be made in a day, but the Committee have missed a great opportunity of pointing out the directions in which the evolution of the midwife's training should be led, and the ideals which should be kept in view. The chief ideal is to provide for the country a body of midwives worthy to form the basis of a national scheme, composed of educated and highly trained women, animated by the esprit de corps of an honourable profession, and adequately remunerated for their work. Only in proportion as some such ideal as this is attained will a national scheme yield the expected result. One step towards this end would be to give midwives a larger share in the management of their own profession, thus developing their sense of responsibility and of the dignity of their work. The administrative changes proposed in the report tend, however, in the opposite direction. Generally speaking, the changes would place the midwives' profession under the control of medical officers of health and nominees of the Ministry, to the practical exclusion of practising midwives and teachers of obstetrics. The most alarming of the administrative changes proposed are indeed those aimed at the weakening of the Central Midwives Board. The main objections to these proposals are clearly set out in the Memorandum of Reservation, signed by Mrs. Bruce Richmond and Dr. J. S. Fairbairn. We trust that this memorandum will be carefully considered before any decision is taken to limit the scope of a body which has done invaluable public service in the past, and which, if it were made more fully representative and given wider powers, would be in a position to do still more useful work in the future.

◆

DYSENTERY IN GREAT BRITAIN.

Dysentery has left a trail of suffering and death all down the ages and still stands supreme as a scourge of armies and camps. A disease which, given suitable circumstances, will so rapidly break out in formidable epidemics, must necessarily have ways of subsisting when times are bad for it—unless we are to believe in spontaneous generation or in gross mutations whereby saprophytes suddenly acquire pathogenic properties together with an array of associated and distinguishing characters. If we follow orthodoxy and disallow such fascinating speculation it follows that the infecting organism must be kept alive in the lean years by a persistence in the carrier state or by a continuous though unobtrusive chain of endemic infections. The evidence for a true carrier state in bacillary dysentery is on the whole negative, and we are left with endemicity as the means by which the causal organism of this disease survives. It is common knowledge that asylums have long been depots of dysenteric infection—a state of affairs which is being coped with successfully by modern energetic measures inspired by a fuller comprehension of the problem. But apart from these, sporadic cases of dysentery and "ulcerative colitis" are far from uncommon in this country and the probability is now almost a certainty that the disease is endemic in many centres; masked, slumbering, and often unheeded, but none the less there. The bacillus survives and only the excellence of our hygienic equipment keeps it under control. In many parts of the Continent, and especially during military manœuvres and in barracks, the disease is a very much more serious menace than it is in Great Britain.

In our last issue (p. 626) we published an article in which Dr. J. A. Charles and Dr. S. M. Warren drew attention to a series of cases of dysentery in Newcastle-upon-Tyne. Their well-documented paper gives a full account of a quasi-epidemic outbreak of this disease in a city where, as Dr. Charles has previously shown[1] there is every reason to believe that it has been endemic for a very long time. Evidence of the kind here adduced makes one suspect that where dysentery has passed out of notice the reason is more likely to be found in a change of nosological fashion than in bacillary inactivity. If the writers of this paper may possibly be accused of a little exaggerating the lack of recognition accorded to the disease in this country—where almost every hospital bacteriologist certainly sees some cases in the course of the year—their criticism of current opinion is nevertheless well founded and they must be congratulated upon the thoroughness with which they have studied an unusually large and significant series of cases. These include 141 examples of proved bacillary dysentery observed between March 1928, and the end of June, 1929, most of them occurring in children between the age of two and the earlier years of school life. A considerably larger number of cases were encountered in which there was good reason to suspect bacillary dysentery but in which bacteriological proof was not obtained. Two types of case were met with: a mild form in which the patient recovered, and a fulminant form which proved fatal within 18 to 24 hours. The deaths, ten in all, were all in cases falling into the second of these categories.

The pathology of bacillary dysentery varies with the type of infecting organism and the acuteness of the disease. In fulminating cases in children the condition is pre-eminently an acute toxæmia and the lesions in the intestine are only trivial; in fact the rapidity of the process almost precludes their development. In adults, fatal cases, which are not common in this country, are most often of the Shiga type in which, if the acute phase is survived, death occurs at the end of an exhausting illness, the patient dying with widespread necrosis of the mucosa of the lower bowel, which is sometimes uniformly involved from the ileocæcal valve to the anus. Such infections are, however, comparatively rare and dysentery as now seen in Britain is usually of the milder Flexner, or the more recently described Sonne, types. There is a good deal of rather confusing detail in the descriptions of serological races of dysentery bacilli, but these are the main indigenous types, and they contributed to Charles and Warren's cases in the proportions of about 4 to 1, with a negligible number of cases due to other types. The Sonne bacillus was found to be somewhat less toxic than the Flexner organism; but the latter, though less virulent for adults than Shiga's bacillus, which is rarely encountered here, may cause a very dangerous infection in children. It is a somewhat curious and unexplained fact that in the series of cases we are considering the mortality was highest not in the very young children, but in boys of 5 to 15 years. In general the mortality was low (7 per cent.) in the proved cases, and this figure no doubt exaggerates the gravity of the infection, since it does not take cognisance of the many mild cases which escaped exact bacteriological diagnosis. It may be worth repeating that all cases other than the fulminating ones recovered; the forms of treatment relied on were salines and serum, and the much discussed bacteriophage was not administered. As regards the fatal cases it is of importance to note that the symptoms of acute fulminating dysentery in the child are sickness, fever, drowsiness, toxæmia, coma, death. The short drama is quickly over and the full intestinal syndrome may never be developed. It is well that this should be widely recognised and that the necessity of expert pathological and bacteriological investigation of all cases of dysenteric infection should be emphasised. The organism is amongst us, and it is a duty to the public and to ourselves to keep tally of it as closely as we may, whilst working steadily towards its elimination.

---

THE CORONER'S AUTHORITY.

HAS a coroner too much power? Some may think so who are accustomed to other forms of judicial tribunal. Two solicitors, attending an inquest lately held at Bournemouth, may have been surprised when the borough coroner refused to allow them to cross-examine witnesses on behalf of parties concerned. The coroner was exercising an indisputable right; he is not only judge but also, so to speak, examining magistrate. He summons such witnesses as he thinks fit and, if he chooses, he can insist on questioning them himself. During the course of the proceedings it may happen to become clear that blame attaches to A or B in respect of the death of X; but A and B have no inherent right to make their defence in the coroner's court; they may even be found guilty of wilful murder on the verdict of the coroner's jury though they have neither been present in court nor been represented by any legal adviser. That is the chief anomaly of the inquest as a judicial tribunal.

The essential element in the proceedings is a dead body, not a specific charge against a named person. The coroner is engaged in collecting and sifting the evidence as a preliminary step to the framing of a charge. Hearsay and gossip are not to be ignored if they help him to reach the facts, nor are the technical rules of evidence to be rigidly followed. His inquiry being of a roving nature, the jury may be invited to range over topics of general interest rather than of strict relevance to the limited issue. Thus at a recent inquest upon the death of a patient in a mental hospital the coroner is reported to have said that it would be for the jury to say whether the hours worked by the hospital staff were not too long. If this meant that the death amounted to manslaughter, caused by the criminal negligence of the hospital management or personnel, it was correctly referred to the jury's arbitrament. If it merely meant that the jury should comment upon the hospital administration, it was one of the vagaries tolerated and encouraged in coroner's courts and in no other judicial tribunals. Anyone who made a collection of the riders attached to the verdicts of coroner's juries would obtain specimens of remarkable range. He would probably also detect similarities in the riders presented to a particular coroner. Sometimes a coroner has views of his own which he does not attempt to hide. Junior barristers, it is believed, when sent to attend an inquest professionally, are occasionally instructed by their more experienced seniors in these idiosyncrasies. The particular topic is respectfully kept in the foreground and the jury adds the appropriate rider.

In view of its autocratic character, the coroner's authority is happy in escaping adverse comment. An independent observer may sometimes be shocked at what he deems the unnecessary publicity and probing into personal affairs in cases of obvious suicide. The legal profession may raise its eyebrows at "coroners' quest law." The general public may wonder whether the inquest should not be brought more closely into line with our other judicial courts. But the inquest is an ancient institution; therefore it is popularly acceptable. The machinery works; therefore time need not be wasted in the invention of a theoretically more perfect process. The statute law was reviewed and amended only three years ago; therefore it is likely to be left untouched for another generation. The ample discretion entrusted to the coroner is not abused by coroners of discretion.

Annotations.

"Ne quid nimis."

NEGLECT OF THE DEAF.

THE National Institute for the Deaf, in its fifth annual report, has endeavoured for the first time in the social history of this country to place before the public in a concise form the full case of the deaf-mute and the deafened. It is evident that the Institute is doing a large amount of valuable work in the face of the severe handicap resulting from lack of interest and support, both from the public and from the Government. Deafness is the most widespread of all sensory disabilities, for the number whom it afflicts in this country probably reaches several millions. It is, therefore, surprising that the total contributions to organisations labouring for the welfare of the deaf and dumb and the deafened over school age should amount only to something under £40,000, while the State stands entirely aloof from such work. In contrast, more than ten times this sum is voluntarily contributed annually for the blind, whose total registered numbers are only some 40,000, while rates and taxes provide a further £600,000. Again, for the blind, the qualification for Old Age Pensions, already reduced to 50 years, will shortly be lowered to 40, but no such consideration is shown to the deaf. At present, education is the only service publicly provided for the deaf, but the Committee of the Institute believes it is certain that the majority of deaf children, despite their far greater need, do not receive an educational opportunity equal to that which is rigidly required for children who can hear. Further, the Committee has recently concluded an inquiry into the industrial position of the deaf and dumb, and has no hesitation in saying that the effects of the large expenditure on education have been, to a great extent, neutralised by the circumstances of post-school life. This is not the result of any lack of effort on the part of the schools or the welfare societies, but is due to the inevitable handicap of deafness in working life, which is increased by modern conditions of industry, by certain legislation affecting wages and insurance schemes, and by the regulations of trade bodies in several industries. As a result, 30 to 50 per cent. of deaf school-leavers remain unemployed. This industrial problem is a pressing one, and it is much to be regretted that the Government in 1928 refused to make any inquiry into the matter. The Institute is raising this question again, and regards it as urgent that an adequate and searching inquiry into the full conditions of the deaf and dumb and the deafened over school age shall be made by the Government in the near future. It is much to be hoped that the Institute will receive the general public support which it deserves.

DIAGNOSIS AND CURE OF G.P.I.

THIRTY years ago general paralysis of the insane was regarded as a definite clinical entity for which there was no cure. It was generally held to be a kind of cerebral exhaustion, due to excessive expenditure of vital energy on "woman and wine." While the diagnosis offered no great difficulty to the experienced alienist, it was made very cautiously, because the outlook was hopeless. The part played by syphilis was subsequently proved beyond reasonable doubt by Noguchi's demonstration of the spirochæte in paralytic brains, and since then the tendency has been to make diagnosis depend on complex laboratory tests for syphilis rather than on observation of the patient's demeanour. The possibility of cure by anti-syphilitic remedies, and recently by induced malarial pyrexia, stimulated efforts at early diagnosis, and thus led to a still greater tendency to diagnose on laboratory findings without waiting for the development of late and unmistakable mental and physical signs. The

Board of Control, having carefully investigated the results of five years of malarial therapy, is satisfied that lengthy remissions, tantamount to cure, have resulted in a goodly proportion of cases, and has definitely pronounced in favour of the method.[1] Malaria is being used more and more, and earlier and earlier; indeed, Dr. G. W. B. James has suggested that it may soon become as essential to do a lumbar puncture, if there is a single sign or symptom suggesting general paralysis, as to take an X ray photograph in a case of injury. But this apparently smooth progress of a new treatment towards universal recognition was interrupted some months ago by a challenge from Dr. John Brander,[2] who roundly questioned the validity of modern diagnosis, and—at the same time—of alleged success in treatment. He believes that serological methods have brought confusion rather than aid to the diagnosis of cerebral syphilis, and that many cases of syphilitic pseudo-paralysis or "insanity with gross brain lesion" are now classed as general paralytics. These, and not cases which would have been so diagnosed by the clinicians of 30 years ago, are the patients who respond to modern therapeutic methods. General paralysis, on the original criteria, is as incurable as ever it was.

To meet this challenge and debate the whole subject the Royal Medico-Psychological Association held a special discussion, and the report of it which has just appeared[3] reveals variety of opinion on almost every point; even the name of the disease is not generally accepted. Dr. Glen Duncan thought that to label any cases "general paralysis of the insane" hampered both psychiatric investigations in general and treatment of individuals, while Dr. James supported Sir James Purves-Stewart's suggestion of the term "progressive syphilitic meningo-encephalitis." The pathology is equally uncertain. While Dr. Nathan Raw's dictum, "no syphilis, no general paralysis" met with general agreement, the theory of the neurotropic stain of spirochæte was not looked upon favourably, Dr. W. A. Caldwell suggesting that the difference in the effects of syphilis depended rather on differences in the soil. Dr. Alexander Walk quoted the French view that ordinary forms of syphilis are allergic, while general paralysis, aortitis, and lingual leucoplakia are anallergic. Dr. B. H. Shaw thought that alcoholism might be the factor which determined whether or not a syphilitic would become a paralytic, while to Dr. F. A. Pickworth the long delay between syphilitic infection and the onset of general paralysis suggested the possible significance of sepsis—e.g., intestinal infection and sphenoidal sinusitis. On the subject of diagnosis there were as many different opinions as there were speakers. Prof. G. M. Robertson thought that no human disease could be diagnosed with such certainty, and based his assurance on a consensus of mental symptoms, physical signs, and laboratory findings. Dr. Hamilton Marr regarded it as a most difficult condition to diagnose, and believed that nine out of ten cases called "general paralysis" during the war were pseudo-paralysis. Prof. J. Shaw Bolton agreed, and pointed out how readily these cases had remitted and how well they had responded to treatment with arsenic and mercury. To some psychiatrists laboratory tests seemed quite unreliable, while others had confidence in some one test, and regarded the remainder with suspicion. Dr. R. M. Stewart had found no one test diagnostic, while Dr. T. S. Good often made his diagnosis on the examination of the cerebro-spinal fluid alone; Dr. Hamilton Marr believed that the colloidal gold test is the most reliable. Dr. Walk did not think there was any tendency nowadays to place too much reliance on laboratory findings; if clinical and laboratory observations could not be correlated, the tendency was to give the clinical side the predominance. Prof. Shaw Bolton laid stress on the existence of a certain degree of confusion of the well-known type as the only reliable mental sign. In the absence of this confusion the prognosis was fairly hopeful, and the disease might remit under any one of several kinds of treatment. Equally varied were the views on treatment. The advocates of malarial therapy pointed to their percentage of remissions. Dr. W. F. Menzies asked whether in the old days, eight successive cases had ever been known to improve, whether treated or not. Dr. B. H. Shaw imagined a history written in A.D. 2500 which dismissed malarial therapy as an amazing and almost incomprehensible obsession. Tryparsamide had its advocates, and in the opinion of Prof. Shaw Bolton had partly justified its claim as a spirochæticide. Between the advocates of malarial treatment there was a difference of opinion on the relative values of the "mosquito" and "blood" methods.

The reader of the report may well agree with Dr. G. Rudolf, as summarised by the President: "that it was impossible to explain the differences in the results obtained by different observers, and that a careful study of the subject made him satisfied that the fallacies were so numerous that nothing definite followed at all." Yet early diagnosis is of the greatest importance if early treatment offers the slightest prospect of cure. As Dr. A. A. Petrie observed, malaria is a dangerous treatment, and its employment is justified only in cases with a very grave prognosis. On the other hand, true general paralysis is such a terrible condition that any alleviating measure ought to be employed at the earliest possible moment. The Royal Medico-Psychological Association has appointed a special subcommittee to consider the treatment of general paralysis, and everyone will hope that this body may be able to reconcile opposing views.

THE INCIDENCE OF VASCULAR SYPHILIS.

NEW interest has been awakened in the pathology and treatment of syphilis by the important discussion upon this subject at Manchester in July.[1] The main points discussed at that meeting were the effects of syphilis upon the cardiovascular system, and there is no doubt that our knowledge concerning these lesions has greatly altered and increased in recent years. We have thus come to realise that syphilitic aortitis is far more common than was previously suspected, and have learnt to diagnose this condition with greater certainty than was formerly possible. In a review[2] of this subject Dr. Bergel and Dr. Rosenthal of Berlin have summarised modern views on the individual incidence of the various forms of syphilis and upon the all-important question of their curability. Collected statistics which they report from Germany covering approximately 70,000 autopsies show that more than 80 per cent. of the syphilitic patients presented involvement of the vessels, and particularly of the aorta. Most clinicians have noted that aortitis is more frequently present in association with tabes or general paralysis than formerly. Rosenthal as a result of careful investigation has no doubt that both syphilitic aortitis and aneurysm have markedly increased among women as well as among men in recent years. He believes, moreover, that the time interval elapsing between primary infection and the first evidence of aortic involvement has strikingly diminished. The cause for such variations in the character of syphilitic infection is not easy to determine. The suggestion that modern salvarsan treatment has tended to alter the disease in the direction of lessening skin affections and increasing nervous and vascular manifestations is supported by some neurologists, but it is clearly a problem that must depend largely upon the exact nature of the treatment employed, and upon the stage of the disease at which it was begun. The fact that both vascular and nervous lesions are now diagnosed at an earlier stage must also be remembered, though in post-mortem material this consideration does not, of course, arise. Prof. Warthin, in his opening paper at the Manchester meeting, stated that latent active lesions are found in the aorta of *every* male syphilitic and in the majority of female syphilitics. Clinically the diagnosis is far less common than this statement *would suggest. The Wassermann reaction is not* always positive in aortic lesions, nor may the signs and symptoms be at all distinctive. Precordial pain, not necessarily amounting to angina, discomfort or oppression over the sternum, a systolic murmur with a ringing aortic second sound but without a raised blood pressure, and X ray evidence of aortic dilatation are our best guides to diagnosis. In the presence of aortic regurgitation or actual aneurysm the difficulties are naturally less, and most clinicians would agree that the presence of an aortic aneurysm is more certain evidence of syphilitic infection than is a positive W.R. in the blood.

[2] Bergel, S., and Rosenthal, O.: Med. Klin., 1929, vol. xxv., Suppl. 6.

Such high incidence of vascular lesions suggests a reconsideration yet again of the curability of syphilis, and the results of treatment as far as they are apparent to-day. There is general agreement that aortitis itself cannot be completely cured, and there is unfortunately no evidence that arsenical preparations have in any way reduced its incidence or mortality. Warthin remarks *that he has never seen at autopsy a case of* perfectly healed syphilis, and that search always reveals active latent lesions in aorta, heart, or other organ. Bergel concludes that syphilis is probably curable only in the first or sero-negative stage, after which true healing is unlikely; and that even with our present methods, though salvarsan is a most potent remedy, actual cure can never be established with any certainty. Even if recovery does take place, Bergel believes that no lasting immunity is conferred and reinfection may thus occasionally occur. It is clear that if this pessimistic attitude is accepted, our sole hope of treatment must lie in early antisyphilitic measures, which must be instituted in the stage of the disease in which the W.R. is still negative. Even at this time, however, a satisfactory percentage of cures can hardly be expected unless at least two full courses of combined arsenobenzol and mercury or bismuth treatment are administered. Such abortive treatment in good hands gives, according to different authors, complete success in between 76 and 100 per cent. of cases, though to a given patient it is never possible to make an absolutely certain reply to his question "am I permanently cured?" Dr. T. E. Osmond, who reviews in this issue the significance of the W.R. at various stages of the disease, states that a case in which treatment is started at the early primary stage will almost invariably continue to give a negative W.R. if the reaction has been negative for a period of one year. Patients beginning treatment at a late primary or a secondary stage may relapse even after giving a negative reaction for two years. It is clear that, as was emphasised by the openers of the discussion at Manchester, the true treatment of cardiac syphilis must be preventive.

NON-OPERATIVE TREATMENT OF SQUINT.

THE main object in the treatment of commencing squint in young children is, of course, to prevent amblyopia in the squinting eye. In the great majority of children Nature provides a safeguard against squint by the development of the impulse to fuse the slightly different images on the two retinæ so as to produce binocular perception. In certain individuals, however, this power of fusion is weak or develops late, and it may even be altogether absent. These are the children who are likely to develop a squint if other factors in the causation of that condition, such as hypermetropia, are present; if the squint is confined to one eye, and is constant, the tendency is for the child to suppress the image formed by the squinting eye. In young children the eye soon becomes amblyopic in the absence of treatment; when the onset of squint is deferred till the child is older the degree of amblyopia is less pronounced, but the longer it has persisted the more difficult it is to overcome. C. A. Worth found[1] that of 193 cases which were brought to him when the duration of the squint was only one-eighth of the life of the patient he was successful in preventing any degree *of amblyopia in 165. In cases where the duration* had been more than one-eighth but less than one-half of the patient's life, the corresponding cases of complete prevention were 73 out of 188, and in the cases where the patient had squinted for more than half his life the complete cures were only 14 out of 604. Besides occlusion of the non-squinting eye the non-operative treatment of squint consists in the training of binocular vision and of the fusion sense. Hitherto this has generally been attempted by means of stereoscopic views and of the amblyoscope, by means of which the child is encouraged to combine the two images presented separately to the two eyes. In practice, however, it is difficult to keep the child's attention on the pictures, however childish these may be. It is to Dr. E. E. Maddox, the inventor of the "Maddox rod," that we owe a new principle in this sort of treatment. By means of his "cheiroscope"[2] the child's hands, as well as his fellow eye, are made to assist in the development of binocular vision. He can trace the outline of a picture visible *to one eye only with a pencil visible to the other eye* alone, or he can play a game of catching a butterfly visible to one eye alone with a net held in the hand of the other side and directed by the other eye. Such devices in the hands of properly trained guides are without doubt a great advance on previous methods. In certain cases they may even effect a complete cure of incipient squint and forestall the necessity of an operation. We understand that a new department at the Royal Westminster Ophthalmic Hospital is about to be equipped with the new apparatus, so that it will have every opportunity of an efficient trial.

TONSILLECTOMY AND PULMONARY ABSCESS.

TONSILLECTOMY is so common an operation that serious complications, even if they occur only in a small proportion of cases, may be responsible for a large amount of serious ill-health. Perhaps the most usual complication is some form of pulmonary inflammation, and the way in which this is produced has often been studied and discussed. Of two main schools of thought one maintains that infected material is inhaled at the time of operation, and the other that the pulmonary lesions are caused by the lodgment of emboli from the site of operation in the pulmonary vessels. The former theory is the more widely accepted, and finds further support in an investigation published in America by Harkavy.[3] He begins by pointing out that one of the reasons cited in favour of the embolic theory is that it is hard to produce inflammation in the lungs of experimental animals by introducing septic material into the bronchial tree, and then he goes on to describe his own experiments in this direction. Using dogs in which the recurrent laryngeal nerves had first been divided and which were anæsthetised by intraperitoneal injection, he introduced, through a cannula passed down a bronchoscope into the terminal branches of the bronchi, 0·5 c.cm of mixed cultures of bacteria along with fresh sputum, both derived from patients suffering from pulmonary abscess following tonsillectomy. *Five out of 27 dogs so treated developed* pulmonary suppuration. The fact that a patient suffers from chronic tonsillitis indicates that he has a low resistance to the particular organism present, and therefore one would expect his lungs to be abnormally vulnerable to infection by such organisms by whatever route they were introduced. The dogs had no such chronic focus of infection from which organisms might be introduced into their lungs, and their resistance might consequently be expected to be higher. This factor may account for the relatively small incidence of suppuration which followed the experiments. Harkavy has certainly shown that it is possible to produce suppuration in the lungs of dogs by direct inoculation with septic material, but it is hard to see how this knowledge will reduce the incidence of pulmonary complications following tonsillectomy. As it is, every possible precaution is taken by surgeons to prevent the inhalation of septic material during these operations, because they are confident, without the reassurance of experiment, that it is a real source of danger.

HOUSING IN THE IRISH FREE STATE.

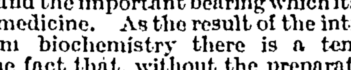
A CENSUS was taken in the Irish Free State in 1926, and that section of the report which deals with the relation of population to housing was published last week. Accepting as the standard of overcrowding the fact of more than two people living in one room, it appears that in the whole country 781,000 persons, or 27·2 per cent. of the population, live in overcrowded conditions. The comparative percentages for Northern Ireland, Scotland, England, and Wales are respectively 18·1, 43·3, 9·8, and 7·2. The Irish Free State is thus shown to be in a better position than Scotland in this respect, but compares unfavourably with Northern Ireland, England, and Wales. The overcrowding in Ireland is worse in the rural areas than in the smaller towns, and among rural areas the worst are those along the western coast, particularly the counties of Donegal, Mayo, and Kerry. It is noteworthy, however, that this overcrowding in the rural areas does not express itself in a higher death-rate. Mayo, for example, with 41·7 per cent. overcrowding has a lower death-rate than the combined 24 best-housed urban districts with an overcrowding of 15·2 per cent. In urban areas there are other influences deleterious to health which more than counterbalance any advantage that may arise from better housing.

EMBOLECTOMY.

To those who cherish the belief that medical practice is international, at any rate on the surgical side, it must come as a surprise to discover that certain operations are frequently practised in some countries while they remain almost unknown in others. The operation of embolectomy illustrates this point. Were it an exceedingly technical and difficult operation, or were there grave reasons for regarding it as undeserving the serious attention of the practitioner, it would be easy to understand why its employment is geographically so patchy. More than 20 years ago Mr. Sampson Handley attempted the removal of an embolus lodged at the bifurcation of the abdominal aorta, and restored for a time the blood current in the femoral artery. He placed the case on record[1] as "one of those pioneer failures on which ultimate success so often rests." His report led Sir Berkeley Moynihan to mention[2] a case under his care at the Leeds Infirmary four years previously, in which an embolus was removed from the popliteal artery and the artery sutured; the patient, who had mitral disease and granular kidneys, died with extensive infarcts five days later. But this work does not seem to have been followed up, and for the most part it has been Scandinavian surgeons at home or in the United States who have taken the lead in this field of surgery. The names of Häggstrom, Key, Lundberg, and Michaëlsson appear in the literature of the subject, and in the public hospitals of Scandinavia this operation has been increasingly performed during the last ten years, the general practitioners in these countries being sufficiently cognisant of the indications for, and prospects of, embolectomy to send their patients to hospital as soon as the correct diagnosis has been made. In *Minnesota Medicine* for May, 1929, the Norwegian surgeon, F. H. Wiese, publishes a case of embolism of the right brachial artery in a woman, aged 64, suffering from heart disease. She awoke one morning with severe pain in the right arm, which was pale, cold, and paralysed. But she was not medically examined till between 6 and 7 P.M., nor was the operation, under local anæsthesia, started until 10.40 P.M., at least 14 hours after the onset of symptoms. Yet the operation was successful, relieving her of severe pain, restoring movement to the arm, and saving her from the gangrene which would eventually have developed, had the operation not been undertaken. Her death seven weeks after the operation from embolism elsewhere in the body, complicated by a three-day attack of pneumonia, emphasises the fairly common observation that this operation is in a certain sense only a palliative. But even then the operation may be justified, as it relieves pain, saves the patient from the much more serious operation of amputation for gangrene, and restores the use of the limb. Dr. Wiese's paper includes a useful summary of the literature.

THE LATE PROF. W. H. PERKIN.

To many doctors the name of Perkin—especially in association with Kipping—will recall little more than a text-book on organic chemistry, which, in their student days, they were compelled, more or less unwillingly, to study. At that early stage of his career the medical student has little time, inclination, or knowledge to grasp the true significance of organic chemistry, and the important bearing which its methods have upon medicine. As the result of the introduction of the term biochemistry there is a tendency to overlook the fact that, without the preparatory work of the pure organic chemist, many of the outstanding achievements of biochemistry would still be in the realm of unsolved problems. The ability to establish the constitution of a complex carbon compound depends upon the skilful application of the methods of organic chemistry, and no sooner has the constitution of a physiologically important natural product been determined—be it hormone or alkaloid or what not—than attempts are made to synthesise it by those same methods. It is in this field of synthetic organic chemistry that the work of Prof. W. H. Perkin, who died last week, has been of such outstanding value. The son of Sir William Perkin, whose discovery of the first aniline dye from coal tar led to the foundation of the modern dye industry, Prof. Perkin was gifted with great technical skill and an amazing facility in overcoming experimental difficulties. He devoted most of his life to elucidating the constitution of some of the most complicated natural products and accomplished synthesis of many of them. At the beginning of his research career he set himself the problem of synthesising compounds containing three, four, or five membered carbon rings—



the possible existence of which was, at that time, scouted by such great organic chemists as Adolf von Bayer—his teacher, Victor Meyer, and Emil Fischer. In spite of this discouragement, which would have been sufficient to make other people hesitate, he persisted, and succeeded in producing such compounds. It would be impossible in small space to give an adequate account of Perkin's contributions to organic chemistry, but a few of his outstanding researches may be recalled, while he originally studied the synthesis of closed carbon chains for its own sake, the methods thus initiated came to be developed and applied to the synthesis of natural products; amongst these, the colourless precursors of the logwood dyes brazilin and hæmatoxylin claimed his attention, and resulted in his assigning to these substances their probable constitution. It is in the group of alkaloids, however, that in recent years he has achieved his greatest success; his work on berberine and cryptopine extended over a number of years, and culminated in the establishment of the constitution of both of these compounds, and in the synthesis of cryptopine. Berberine, as its name implies, occurs in the root bark of the barberry, *Berberis vulgaris*, but is fairly widely distributed in the vegetable kingdom, occurring in plants belonging to the natural orders of Papaveraceæ, Ranunculaceæ, and Rutaceæ among others. Cryptopine, on the other hand, is a much rarer alkaloid, being obtained only from opium, where it occurs in the filtrate remaining after the removal of morphine and thebaine. Two other rather uncommon alkaloids, harmaline and harmine, occurring in the seeds of *Peganum harmala*, which have been used in the treatment of malaria, were also investigated by Perkin, and after showing them to be derived from hydroxytryptophane he succeeded in synthesising both of them. In 1910 he proposed a formula for strychnine which was generally accepted, and placed this compound among the derivatives of quinoline; but last year he put forward a modified formula according to which strychnine becomes a derivative of *iso*quinoline. This derivation would, of course, have a profound influence upon the course to be followed in its synthesis—an object which it was Perkin's great ambition to accomplish. Perkin's charm of manner and natural gift for imparting knowledge to others endeared him to all with whom he came into contact. His relations with his colleagues were always cordial, and he was generous in acknowledging the help he received from them. Fortunately for chemistry in this country he has left behind him a number of his former pupils, who are imbued with his spirit and can be relied upon to carry on his work in a worthy manner.

VENEREAL DISEASE ON THE CHINA STATION.

VENEREAL disease is a serious matter for the armed forces of the Powers in China, where it attacks at least three or four times as large a proportion of the men as at home. We know relatively little about what happens among troops other than our own, and a paper [1] by Dr. Cazeneuve, on cases of venereal disease among the French in 1927, is therefore instructive. He gives the percentage prevalence of these cases in the French Squadron in China for several years, and to this we have added the similar figures from the Royal Navy, though it may well be that the methods of enumeration are not precisely the same, and the figures not truly comparable. They are as follows :—

—	French Squadron.	British Squadron.	Army at Shanghai.
1900	13·7	18·3	—
1903	12	16·9	—
1907	15·3	18·3	—
1925	12·9	21·2	—
1926	10·7	17·4	—
1927	20·2	13·7	22·3
Number of men in 1927	1551	13,200	8,079

We may add the stated differentiation of cases (not first infections) :—

Soft chancre	0·6	3·5	8·9
Gonorrhœa	8·1	8·4	11·6
Syphilis	2·5	1·8	1·6

Dr. Cazeneuve is concerned about the increase in venereal disease which he has observed during his service in China, and ascribes it primarily to the want of employment for men on leave and to the flooding of Chinese ports with prostitutes. Before 1911, he says, the Chinese kept their women away from the foreigner, but since the Revolution and the emancipation of women, excited young students, with "liberty" on their lips, are much in evidence, whilst the uneducated women of the poorer classes have adopted the new manners, and by reason of famine and poverty crowd into the foreign concessions. Japanese women have left China since 1914, but after the late war the Russians began to come down from Siberia, "many with no resources but their good looks"; they have had no one to take thought for them or look after them, and they it is who are the greatest danger to the sailor. Under these conditions venereal diseases themselves have become clinically more serious—a conclusion which Dr. Cazeneuve reaches because: (1) all three infections often result from a single risk; (2) some of the syphilitic cases are very severe; (3) chronic buboes follow 10 per cent. of the soft chancres; and (4) one-third of the hard chancres appear over the site of a soft chancre, suggesting simultaneous double infection. Much is done in the French Navy, he says, to prevent men from risking infection. Newcomers are warned, in classes of ten, that continence is the only true safeguard, and patients are enlisted as lay preachers in the same cause. Each man must take ashore the "nécessaire de poche" or prophylactic packet, but he is warned that these ointments protect less in China, where the disease is very infectious, than in Europe. Of 140 cases more than half professed they had availed themselves of the usual prophylactics, but of 233 who passed through the ablution chamber on board 75 per cent. escaped infection. Dr. Cazeneuve has great hope from the recreation room opened and the welfare work instituted for French sailors at Shanghai, though infections occur, of course, at other ports. Like many others he notes that the people who get themselves into trouble by indiscipline and carelessness on board are just those most liable to contract venereal disease ashore. What he says of the increase of prostitution in China is no doubt true, and when he says that venereal disease is there more severe than formerly he is in agreement with other writers; but it is to be noted that the time of each case under treatment and the proportional occurrence of all diseases but soft chancre have decreased in the Navy in the last four years reported (1924–27). This is probably due to the measures of welfare work he mentions, and to the accommodation of treatment to the local climatic conditions, but obviously it may be partly the result of special distribution of the ships in the various ports about the station, with a lessening of risk, for which no allowance can be made in the general statistics. That the figures are improving nevertheless raises our hopes that the toll taken by these serious diseases will further decrease, especially when medical officers have had time to study Dr. Cazeneuve's careful appreciation of the local situation.

THE PHYSIOLOGY OF MILK PRODUCTION.

THE National Institute for Research in Dairying has for its chief aim the creation of a healthy industry, and in its early days the Institute at Reading demonstrated the losses occasioned by faulty milk and the methods to prevent these losses. This work has been of value to the Ministries of Health and of Agriculture, providing the former with the means of establishing standards of cleanliness for milk, and the latter with the basis of an educational campaign. Dairymen are now beginning to recognise that a cleaner milk is worth more money and are paying for it on a quality basis. The farmer is thus reaping the benefits to be derived from a healthy industry and the consumer is getting a sounder food-stuff. The same policy has been adopted towards the problem of milk carrying disease, particularly tuberculosis. The Institute has demonstrated the grave losses caused by bovine tuberculosis and has investigated the means by which it is spread in dairy herds, and the need for the more extended use of the tuberculin test. The steadily increasing number of non-reacting herds throughout Great Britain, and especially within a short radius of the Institute, is gratifying evidence of the influence of this work. The annual report [1] of the Institute for 1928, while it recognises all this shows that more is necessary if a complete picture of the reasons for the varying constitution of milk is to be obtained. It has long been known that the proportions of fat and of solids-not-fat in milk of different breeds of cows vary widely, but it has now been shown that the variation is present in the milk of cows of the same breed, even when they are managed under the same conditions. It is probable, too, that the constitution of milk has a profound influence on the type of ripening which takes place in dairy products and may help to explain the differences which are found to occur in the maturing of cheese of the same character in different parts of the country. These considerations led to the study of the detailed constitution of milk, and one of the first discoveries was that in milk fever in cows the calcium balance of the blood is profoundly disturbed and that the administration of calcium has some value. Further work has made it possible to formulate a theory of secretion which will account for the high concentration of calcium in the milk as compared with that found in the blood of the cow. Since then the presence of calcium and its state in milk are of importance alike to the health of cattle and to the manufacture of many dairy products work was continued at the Institute on these lines. By feeding experiments it was shown that the presence of vitamin D increases the percentage of total calcium in milk, and in the laboratory that the relative proportions of diffusible and indiffusible calcium in milk are affected by even moderate heat. The latter observation may be of importance to the industry, since the curdling of milk for cheese is largely dependent on the quantity and state of the calcium which it contains. It may also prove more important to human nutrition than has been suspected hitherto. Many of the observations will hardly be fully explained until a more thorough study has been made of the physiology of milk secretion, and of the influence of the constitution of food-stuffs upon the final composition of milk. The report contains an urgent appeal, supported by many eminent physiologists, for means to set up a department of physiology within the Institute. We wish success to this effort in view of the importance to medicine of the work that is being done there.

TROPICAL FEVERS OF SHORT DURATION.

ALTHOUGH in prolonged infections the ætiological agents, such as the malaria parasite, the relapsing fever spirochæte, and the micro-organisms of undulant fever and the enteric group are readily isolated or identified, it is by no means always possible to ascertain the cause of fevers of shorter duration. The nature of these *febriculæ* varies considerably in different countries and the differential diagnosis is largely determined by geographical distribution. In fevers such as dengue, phlebotomus, and yellow fever, which may be extremely prevalent in a zone of military operations, the ætiological agent has not yet been recognised, so laboratory aids to diagnosis are confined to the more indirect reactions, such as the cytological response in the blood. A reduction in the total number of leucocytes may characterise all three of these infections, though the minor variations in the character, number, size, and shape of the different types of leucocytes may be actually misleading if too much attention is paid to them. A leucocytosis is found in relapsing fever, amœbic hepatitis, influenza, and less commonly in Weil's disease. The latter presents a special problem, for, although the leptospira may be abundant in the blood stream it cannot usually be demonstrated in a stained blood-film preparation, so that recourse must be had to animal inoculation and the reproduction of a disease with the characteristic pathology in the guinea-pig. Considerable assistance in diagnosis may, however, be obtained from microscopical examination of the centrifuged urine when the leptospira may often be demonstrated even in mild transient cases. Albuminuria occurs in Weil's disease as well as in yellow fever, but in the latter it is usually more intense; yet this well-known feature of differential diagnosis may be wanting in transient attacks of yellow fever unaccompanied by jaundice or the well-known stigmata of the disease, which, judging from the work of Hindle and other recent investigators of the yellow fever virus, probably precede and accompany every widespread epidemic. Serological reactions such as the specific agglutination of the organisms of the enteric group may be greatly delayed, especially in paratyphoid fevers, and no clumping of the organisms may be obtainable till convalescence has been well established. This is found usually in paratyphoid A infections, where the titre of agglutination may not be a high one and may appear only a week or more after the symptoms have subsided. In undulant fever of short duration, of which examples rarely occur, a further difficulty may present itself in what is known as the paradoxical reaction, or the zones of no reaction. Here no agglutination is obtained in low dilutions, but only in titres above 1 : 100, so that unless a suitable range of dilutions is made the diagnosis will certainly be missed. In typhus fever, even in mild and transient cases, the Weil-Felix reaction is of great diagnostic value, though the rationale of this reaction is by no means clear. By some it is held that slight degrees of insolation may produce pyrexia, and we believe this to be possible in susceptible individuals and especially in children. A certain proportion of cases, even in the most ideal conditions, will have to be given the depressing and well-worn label "pyrexia of unknown origin," though it might conveniently be replaced by that of "tropical fever of short duration." It was under this heading that the subject was fully discussed at the Fifth International Congress of Military Medicine and Pharmacy held in London last May. The official report of the Congress has now appeared and contains summaries of communications from medical officers from the Mediterranean stations, the French colonies in Africa, Greece, and Japan. Reports were also submitted by representatives of our own Army, Navy, and Air Force. The outcome of the discussions was, as would have been expected, that the correct classification of these fevers of short duration can only be obtained by due appreciation of the limitation of laboratory tests and the intelligent correlation of the laboratory findings with the clinical aspects of the case.

OUR CHANGE OF ADDRESS.

DURING the first 25 years of its life THE LANCET changed its home four times. For over 80 years, however, it has been published from the building at the corner where Bedford-street joins the Strand. The lease of this building having nearly expired, the proprietors of THE LANCET have acquired the freehold of an 18th-century house at No. 7, Adam-street, Adelphi, to which the offices of the journal will be transferred in the middle of next month. The Editor will be At Home on Wednesday, Oct. 16th at the new premises from 9 P.M. Admission will be by personal invitation, which will be sent if application is made to the Manager before Oct. 5th.

LAST week in the presence of representatives of the State of Hesse, a formal presentation of 4½ million marks, the equivalent of £225,000, was made to Nauheim Spa by an unnamed American in gratitude for her treatment there. The sum of 2 million marks is to go to a fund for endowing scientific work, an account of which will be given in an annual lecture of the Institute for which the remaining 2½ million marks is allocated. The Institute will include four sections: (1) for investigating patients sent to Nauheim under the social insurance scheme; (2) for statistical work into the causes of cardiac disease; (3) for social instruction on the causes and prevention of cardiac disease; (4) for experimental pathology and therapy. The Institute will give all the doctors in practice at the spa the opportunity of research, access to the newest medical literature, and a medical museum as well as a conference hall. The building is to be erected opposite Bath House No. 8, and is to be begun at once. Gratitude could hardly have taken a more beneficent form.

WE regret to announce the death, on Sept. 22nd, after a long illness, of Ernest Edward Glynn, late professor of pathology in the University of Liverpool and honorary pathologist to the Liverpool Royal Infirmary.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

XLV.

INTERPRETATION OF THE WASSERMANN REACTION IN ADULTS.

PART II.*—POSITIVE, NEGATIVE, AND DOUBTFUL REACTIONS.

Positive Results.

PROVIDED that a satisfactory technique is employed, and the test carried out by a competent pathologist a positive Wassermann reaction (+ + or +) means that the patient is infected with syphilis—recent or remote. The only exception to this rule is "yaws," which also gives a positive W.R. However, since this disease is almost unknown in this country, and very similar to syphilis both in its clinical manifestations and reaction to treatment, whilst the causal organisms are indistinguishable, the exception has little practical significance.

Most text-books give a list, more or less long, of diseases in which the W.R. *may* be positive. Amongst these are included fevers of all kinds, especially typhus, typhoid, and pneumonia; scarlatina, malaria, tuberculosis, Vincent's angina; leprosy, especially the nodular variety; diabetes, nephritis, jaundice, thyroid disease, tumours of various kinds, lead poisoning; various skin diseases, including psoriasis, urticaria, pigmentosa, erythema iris; a number of tropical diseases, including trypanosomiasis, relapsing fever, pellagra, tropical ulcer, and beri-beri. In addition also, positive results have been recorded during pregnancy and general anæsthesia, and in sera from persons in articulo mortis and from cadavers. With the exception of yaws, however, none of these gives a consistently positive W.R. The majority can be excluded either as occurring very rarely in this country or because the differential diagnosis is easy. Scarlet fever has been reported as giving as many as 5 per cent. of positives—but I have personally tested more than 100 in all stages of the disease without obtaining a single positive result. Malaria is said to be particularly likely to give the reaction at the height of the fever; I can only say that this is not my experience, either in this country or in India, though in the latter country I have obtained a number of doubtful reactions when working in very high temperatures where the reagents, particularly the complement, were unsatisfactory and of very low titre. Few diseases have not at some time or other been implicated, but none has stood the test of time; as the technique of the W.R. has been improved so gradually the list has tended to shorten. Where a positive result is obtained and confirmed by retesting in any of the above, it will nearly always be found that syphilis is present as well if a careful investigation is made into the history and clinical side of the case.

Skin diseases are the ones which tend to cause most difficulty because of their resemblance to syphilis; of the three mentioned psoriasis has given a number of border-line reactions in my hands, but I have no special experience of the other two; in most cases there should be little difficulty, because if the lesion is syphilitic the blood will almost certainly show the strongest positive reactions, whereas non-syphilitic lesions are not likely to give more than a very weak positive result. In such cases the therapeutic test may be employed; a few injections of arsenic will nearly always clear up a syphilitic skin lesion; those due to other causes will not be benefited. This procedure should only be adopted in the last resort, and by none but experienced workers. In this connexion it is well to point out that, with the exceptions stated, a positive W.R. means syphilis; but it does *not* mean that all the patient's signs and symptoms are due to syphilis. A syphilitic patient may suffer from other diseases, and failure to afford full recognition of this fact has tended to bring both the W.R. and antisyphilitic remedies into disrepute.

Another possible explanation of a "false" positive result is an error in technique. Even the most careful and experienced pathologist may make a mistake, particularly in so complicated a reaction as the Wassermann. Moreover, confusion of specimens may occasionally occur in the best managed laboratories. J. A. Kolmer[1] states that minute amounts of acid or alkali present in the tubes or pipettes used may be the cause of a false positive, owing to their effect on complement. Over a long series of tests the occurrence of false positives should not exceed 0·2 per cent. Kolmer gives his incidence as less than 0·1 per cent. During the last nine years I have tested an average of 8000 tests annually, and I have found less than one false positive in 800 tests.

For the above and other obvious reasons it is evident that no case should be labelled syphilis on the strength of a single isolated positive W.R. where the history and clinical signs are against such a diagnosis. The test should be repeated—preferably on another specimen—and if still positive should, if possible, be confirmed by one or more of the various flocculation tests, such as the Kahn or Sigma.

Negative Reactions.

A negative reaction—especially an isolated one—does not absolutely exclude syphilis, especially where the history or physical signs point to a diagnosis of this disease. Early syphilis, before antibody has had time to be formed, treated syphilis, and the congenital variety in adults may be expected to give a negative result. Alcohol has been stated by C. F. Craig to convert, temporarily, a positive reaction to negative; but in an experience of nearly 100,000 tests I have never met this. Kolmer states that it is not his experience. Pregnancy is also stated to be the cause of occasional false negative reactions.

Another important point in this connexion is the almost daily variation in the antibody response to syphilitic infection: the fluctuating W.R.—on one occasion positive, and on another negative—is now recognised by most workers. This and other considerations demand that a negative reaction should be obtained on at least two occasions before excluding syphilis. Two or more negative reactions may be expected to exclude *active* syphilis in at least 90 per cent. of cases. Where an unexpected negative reaction is given, a provocative dose of arsenobenzol may be given as described below, and one or more of the flocculation tests carried out.

Doubtful Reactions.

A doubtful or "border-line" reaction, variously recorded as weak positive, weak negative, ±, is not sufficient alone to establish a diagnosis of syphilis, but may usually be taken as an indication for a further investigation of the case, both clinical and pathological. It frequently occurs in the early primary stage—e.g., a few days after the appearance of a primary sore; fortunately it is usually possible to clinch the diagnosis in such a case by finding the

---

* Part I., on Indications, Methods, and Notation, appeared last week.

[1] Serum Diagnosis by Complement Fixation, Baillière, Tindall and Cox, 1929.

Tp. pallidum either in the sore or in a neighbouring lymphatic gland. On the other hand, when such a reaction is given by the serum of a syphilitic patient who is having, or has had, treatment it is an indication for further treatment.

Where the diagnosis is in doubt, the test should be repeated, preferably after a "provocative" injection of arsenobenzol—e.g., 0·3–0·45 g. neosalvarsan given intravenously. The blood should be taken for retesting 2, 7, 13, and 21 days later; if only one retest is possible, the seventh day after the injection should be chosen. It is quite common to find that the provocative injection will convert a negative or ± reaction into a frank positive in a case of syphilis. This is probably intimately connected with the well-known Jarisch-Herxheimer reaction (a temporary exacerbation of the symptoms), which is said to be due to the destruction of spirochætes and liberation of their toxins. In any case, and more especially when the patient is under treatment for syphilis, it is well to confirm (or otherwise) a doubtful reaction with one or more of the flocculation tests. These reactions are for the most part more sensitive in treated cases than the W.R.

The following table gives the percentages of positive results found in the various stages of syphilis. It refers only to untreated cases, since the amount of treatment and the time elapsed since it was discontinued will vary, and the results would be of little value unless particulars were given in every case. The figures are the mean of those of a number of workers, including Kolmer, Craig,[2] L. W. Harrison,[3] and others.

—	Days after appearance of sore.	Per cent. positive.	—	Per cent. positive.
Primary S.	5–14	44	Tertiary S	80–97
	10–14	75	Latent S.	64–80
	21–28	82	Tabes	70–90
	28–42	94	G.P.I.	100
Secondary S.	—	98–100	C.S.S.	60–75

C.S.S. = Cerebro-spinal syphilis.

It is quite clear that in the very early stage of syphilis a large proportion of negative Wassermann reactions is to be expected, but none the less it is important that the reaction should be carried out *in every case* before commencing treatment, because the prognosis is so much better in a Wassermann-negative than in a Wassermann-positive case; it is as well to repeat the test a few days after the first or second injection of arsenobenzol, since these may convert a negative to a positive reaction (provocative effect). A negative W.R. in the presence of active syphilis is not unlikely to occur in pregnant women and in the vascular types of the disease, but in any stage of the disease a negative W.R. may be met with and the reaction should always be repeated in face of evident signs of the disease.

Effect of Treatment.

L. W. Harrison says: "There is no doubt that the Wassermann test, in conjunction with clinical signs, is a far better guide to the immediate effect of treatment than clinical signs alone." In the large majority of cases treatment may be expected to convert a positive W.R. to negative; generally speaking, when the treatment is begun in the early stages of the disease the W.R. usually becomes negative rapidly. Conversely, when the disease has existed for a number of years—e.g., in tertiary syphilis—very prolonged and energetic treatment is usually required. In primary syphilis the W.R. usually disappears in three weeks, and in nearly 90 per cent. of cases in six weeks; in secondary syphilis it is common to find the W.R. negative by the end of the first course (say 12 weeks). In later syphilis much more time and treatment are usually required, depending on a number of factors.

When the reaction has been converted to negative, it is of the utmost importance not to discontinue treatment but to follow up within a few weeks, because it is a common observation that a W.R. which relapses is extremely difficult to convert to negative again. The amount of treatment required must be determined individually for every case, but it is usually found that at least one course of treatment (say ten weekly injections of arsenobenzol and bismuth or mercury) is necessary after the W.R. has become negative. The sooner the W.R. becomes negative the better the ultimate prognosis, but it cannot be too strongly urged that a single negative W.R. must never be accepted as proof of cure of the disease. A ± or doubtful reaction occurring during treatment may usually be regarded as positive—that is to say, it means that more treatment is required; it should never be disregarded.

A Quantitative Test.

In order to observe closely the effect of treatment some form of quantitative test is desirable. Where at the end of a course of treatment the W.R. is reported as still + + (strongly positive), the clinician is in the dark as to what effect his treatment has had. For this purpose I have in the past tested out a series of dilutions of the patient's serum—e.g., 1/10, 1/15, 1/20, and so on, to 1/100—1/5 being the dilution ordinarily employed. In this way an end-point can always be reached. When a serum is reported as positive at 1/100 before treatment, positive at 1/50 after one course, and positive at 1/20 after a second course (though in each case the routine report would be "strongly positive"), both doctor and patient will be encouraged to continue with treatment. An even more satisfactory way of arriving at the same result is to have recourse to the Sigma test, which records results in units; thus under treatment a case of tertiary syphilis may fall from 20 units to 7·5 in three months, and in six months to 2·5 (1·5 units or more are considered positive for diagnosis, and 1·0 or more for test of cure). A quantitative test is not a necessity, but it is often of value in estimating the effect of treatment and in persuading the patient to persist in a treatment which may be long and irksome.

Effect of Different Drugs.

The drugs which have most effect on the W.R. are arsenobenzol (in its various forms), bismuth, and mercury (given by inunction or injection) in that order. Mercury by the mouth has little if any effect—and I believe the iodides have none. By this I do not mean that mercury or iodide should not be given by the mouth, but that they have no direct effect on the W.R.

Test of Cure.

In order to establish presumptive cure the W.R. should be consistently negative over a period of *at least* two years following cessation of treatment. It is usual to test the blood at the conclusion of treatment, and thereafter every three months during the first year, and six-monthly during the second year. The tests at the end of each year should be preceded by a provocative injection, and the last test should be accompanied by an examination of the cerebrospinal fluid. Experience has shown that an early primary case which remains negative for a year will almost invariably continue negative. A late primary or a secondary may relapse even after being negative for two years. If a patient has relapsed after a given amount of treatment or has not commenced treatment till a later stage than those mentioned above, no guarantee can be given that the reaction will not return if treatment is suspended for any considerable length of time.

What is of importance is that if a given patient is going to relapse he will usually relapse serologically before he does so clinically. Hence the value of repeated blood tests.

[2] Craig, C. F.: The Wassermann Test, Henry Kimpton, 1921.

[3] The Diagnosis and Treatment of Venereal Diseases in General Practice. Third edition. 1926. Oxford University Press.

Persistent Positive W.R.

Not infrequently a patient will continue to give a positive W.R. after repeated courses of treatment, and the question arises will it *ever* be possible to convert the W.R. to negative? May not the patient be already cured? It is my firm opinion that a strongly positive W.R. means that *living spirochætes* are lodged somewhere in the patient's tissues. If quantitative tests of some kind are carried out it will usually be found that there is a slow but progressive fall in the strength of the reaction, so that if treatment is persisted in a negative result will generally be obtained in the long run. Kolmer says: "I have seen so many relapses follow the cessation of specific medication among those tired of the 'tyranny' of persistently positive reactions . . . that I believe a very heavy responsibility rests upon any physician . . . who deliberately ignores them in the treatment of the disease." Such patients require continued observation and periodic courses of treatment, even, in some cases, for the remainder of their lives.

The Influence of Pregnancy.

It has often been stated that false positives occur in pregnancy, but this is not my experience. Kolmer states that the opposite holds, and that pregnancy may be the cause of false negatives; and this also applies to the lactation period. A single negative, therefore, should not be trusted. A syphilitic mother with a negative W.R. may produce a syphilitic child.

Congenital syphilis in children has already been dealt with in this series of articles,[4] but it should be pointed out here that the W.R. *tends to die out* as they grow up, so that adolescents and young adults may show a negative reaction. Kolmer states that in young adults with latent syphilis 40 per cent. of positives may be expected, whilst those with skeletal lesions will give 70 per cent. of positives. He also states that 80 per cent. of the fathers and 60 to 90 per cent. of the mothers of syphilitic children give positive reactions. There can be little doubt that the mother of a syphilitic child is herself nearly always syphilitic, even though she may be apparently healthy. Both parents of a syphilitic child should always have their bloods tested.

Examination of Cerebro-spinal Fluid.[5]

The technique of collecting a specimen is hardly within the scope of this article. Like many other procedures, it is easy for those who are accustomed to do it, but often difficult for the uninitiated. It is not an operation to be undertaken lightly on account of the somewhat severe headache which may follow withdrawal of the fluid; moreover, it is not always convenient for the patient to keep his bed for at least two days as he should. On the other hand it should never be shirked where there are clear indications for its performance.

The special indications for testing the cerebro-spinal fluid are: (1) test of cure; (2) any suspicion of involvement of the central nervous system; (3) a persistently positive W.R. in the blood.

About 5 c.cm. is a convenient quantity to draw off and this should be clear and free from blood. The cerebro-spinal fluid usually contains much less Wassermann-reacting substance than the serum and therefore the W.R. is carried *out in rather a different* way. *Varying amounts of the fluid* are tested with fixed amounts of the other reagents, and the results are returned as 4, 3, 2, or 1, plus and negative. Four, three, and two plus are considered definitely positive, one plus as doubtful. It does not seem to be generally known that changes occur in the cerebro-spinal fluid not uncommonly in the early stages of syphilis. O. H. Mills, at Rochester Row, found changes in the fluids of 47 per cent. of secondary cases. It should also be remembered that a patient may have a positive cerebro-spinal fluid with a negative blood. Kolmer gives the following table of incidence in the various stages of syphilis:—

	Positive W.R. per cent. in C.S.F.
Late primary and secondary	30–40
Asymptomatic, early, untreated	30–40
„ late, ...	80–90
Tabes	90
Paresis	100
Cerebro-spinal syphilis	96–100

It is not suggested that it is necessary or even desirable to examine the cerebro-spinal fluid of every case of early syphilis, but the frequency with which the nervous system is involved is of interest. Under the influence of treatment the early cases quickly show a negative reaction; syphilis of the supporting structures is also fairly amenable to treatment. Tabes often *shows considerable weakening of the reaction,* but G.P.I. is most intractable except in the most favourable cases under the influence of malaria therapy combined with arsenobenzol.

A positive W.R. in the cerebro-spinal fluid is even more specific than in the serum, though there are often no changes in the fluid in cases of syphilitic arteritis of the cerebral vessels. Moreover, the W.R. is far superior in sensitiveness and specificity to most, if not all of the flocculation reactions.

It is customary to perform three other types of test on the cerebro-spinal fluid, since these help to confirm the W.R.

(1) Estimation of the number of cells, which are usually small lymphocytes. Less than 5 per c.mm. may be considered normal, 5 to 10 doubtful, and more than 10 positive.

(2) *Globulin* cannot be demonstrated in a normal fluid. Excess is commonly present in syphilis of the central nervous system, though it should be pointed out that excess neither of lymphocytes nor of globulin proves that the pathological process is syphilitic.

(3) *Colloidal reactions*, such as the Lange gold-sol, benzoin, and mastic reactions. Various curves are used to record the results of these, the most diagnostic being that attributed to G.P.I., in which there is precipitation of the colloid with the lower dilutions of the fluid, tailing off gradually to none with the higher dilutions. Tabetic and luetic curves are also described.

A negative fluid should be negative to all three of these types of test, as well as to the W.R., since these reactions tend to run parallel, though some react to treatment more readily than others.

Summary.

(1) The Wassermann reaction is highly complicated. Choose a sound technique, a reliable pathologist, and a good laboratory. For purposes of comparing results at various stages in the treatment it is better to keep to the same pathologist and the same technique.

(2) See that the specimen is ample in amount and of good quality.

(3) Give the pathologist all the information which may be helpful and ask for his opinion on the interpretation of the result.

(4) A positive result nearly always means syphilis. If there is a doubt it should be repeated and confirmed.

(5) One negative result does not exclude syphilis; two or more usually do.

(6) Mistrust "weak positives" and "doubtfuls" where the diagnosis is in question.

(7) When treating a case of syphilis have the blood tested frequently—a serological relapse precedes a clinical one.

(8) To establish a cure time is just as important as negative Wassermann reactions.

T. E. OSMOND, M.B. Camb.,
Pathologist, Venereal Diseases Dept., St. Thomas's Hospital, London.

[4] Nabarro, D. N.: THE LANCET, 1929, i., 90.

[5] This subject has been dealt with in detail in this series by Dr. J. G. Greenfield: THE LANCET, 1928, ii., 716.

either by training or experience, to be given complete freedom in the use of such drugs.

When a midwife has ceased to practise for a considerable period and desires to resume midwifery work, or where a midwife although in practice has attended an insufficient number of cases to remain efficient, the local supervising authority should be empowered to represent these facts to the Central Midwives Board, in order that the Board may determine whether the midwife should be required to undergo post-certificate instruction.

The local supervising authority should have power n cases of this nature to suspend the midwife from practice, pending the promulgation of the Board's decision.

Section E of the rules of the Central Midwives Board, whether or not retained in its position of statutory authority, requires to be revised and rearranged.

Administration.

Supervision of Midwives.—There is a lack of uniformity in the arrangements adopted by local supervising authorities for the supervision of midwives, due to the absence of any standard qualification for inspectors of midwives, and the following changes are desirable :—

Medical Inspectors.—(*a*) Wherever possible, every new appointment to the post of chief inspector of midwives should be given to a medical officer who has had actual experience of obstetric practice and who is engaged on other work of a similar nature—e.g., as an assistant medical officer for maternity and child welfare.

Non-medical Inspectors.—(*b*) Subordinate positions for routine inspections should be filled, when vacancies arise, by midwives who are trained nurses and have had long experience in the actual practice of midwifery. It would be in the interests of midwives if the Minister of Health were given power to prescribe the qualifications that should be held by inspectors of this class.

Midwives should have ready access to the medical inspector. The employment of health visitors with little or no practical experience of midwifery for the inspection of midwives is to be deprecated.

The dual routine inspection of particular midwives who practise in the area of more than one local supervising authority is highly objectionable.

Central Midwives Board.

This Board has dealt with the intricate problems confronting it with good judgment, but certain alterations in its powers and duties are desirable.

The present system of discipline under which midwives are punished for failure to comply with the rules prescribed by the Central Midwives Board, in view of the improved status of the profession, be altered on the lines indicated below :—

(*a*) The Board should be given general power (1) to suspend, or when necessary to erase from the roll the name of any midwife found guilty of a felony, misdemeanour, or offence which, in the Board's opinion, renders her unfit to practise ; and (2) to caution, suspend, or remove from the roll a midwife who, after due inquiry, is judged by the Board to have been guilty of conduct in any professional respect which makes her unfit to pursue her calling, or of a midwife who carries on her work in such a way as to endanger the health or life of the mother or child. (*b*) If the Board were given these powers the existing rules which regulate, supervise, and restrict the practice of midwives could be relegated from their present position of definite statutory authority and penal significance to a less commanding, but still important place. To this end the Board might issue to every midwife practising in England and Wales warning notices or instructions.

It would be an advantage if the Board were to appoint an independent legal assessor whose opinion would be available at penal proceedings.

Power should be conferred on the Board to subpœna witnesses and to require evidence on oath and the production of documents.

Where a local supervising authority represents a prima facie case of negligence, malpractice, or misconduct to the Board, the prosecution of the charge should rest solely with the authority ; it should be competent for any other interested body or individual complainant to bring a case before the Board in the same way. In a residuum of cases the Board must take action on its own initiative.

Existing arrangements for the approval and inspection of training institutions and teachers by the Central Midwives Board are unsatisfactory by reason of their extremely limited scope. The whole of this work should be placed in the hands of the Minister of Health, on whose behalf the majority of the institutions recognised as training schools by the Board are at present inspected by officers of his department, either in connexion with grants in aid of midwifery services or the training of midwives, or as part of the routine inspections of poor-law institutions. An advisory committee, consisting of persons appointed by the Minister of Health on the nomination of representative bodies (including the Central Midwives Board) should be formed to advise the Minister regarding matters coming within the scope of his inspecting and approving duties.

The duty of formulating the course and length of training should also pass from the Central Midwives Board to the Minister of Health.

In order to keep the work connected with the examining of pupil midwives apart, both in personnel and association, from the judicial functions of the Board, an examinations board should be appointed which should be directly answerable to the Central Midwives Board for the conduct of its duties. It would be of great advantage for the advisory committee to the Minister of Health to be represented on the examinations board.

If effect is given to these recommendations the functions of the Board, besides keeping the roll of midwives, would be mainly disciplinary, and it would then be possible and advantageous to constitute the Board with a small compact membership.

Members of the Board might serve for a period of five years and be eligible for re-election or renomination as the case may be.

Provision should be made to secure the payment to members of the Board of a specific fee for attendance at meetings.

Sundry Recommendations.

The scale prescribed for the payment of the *fee of a doctor* called in by a midwife in a case of emergency should be reconsidered by the Minister of Health in consultation with the local supervising authorities and the British Medical Association.

The time limit of two months imposed for the presentation of a doctor's account to the local supervising authority should be extended to three months.

The attempts which have been made by law to prevent the *practice as midwives of uncertified women* have largely failed in their object, and it would seem that the remedy for this abuse can best be found in the application of a State maternity scheme.

It is highly important that the nursing of women during the puerperium should, in general, be carried out by a certified midwife. The practice followed by certain hospitals of training women as maternity nurses is open to objection, and should cease as soon as possible.

The duties of a *home help* should be strictly limited to the ordering and care of the household as usually carried out by the mother herself. Nursing duties do not come within her province.

Use of Anæsthetics in Confinement.—It would be in the public interest if some professional body would take upon itself the responsibility for issuing at an early date some pronouncement as to the advisability and place in labour not only of anæsthetics, but also of analgesic and sedative drugs generally.

RESERVATIONS.

Dr. J. S. Fairbairn and Mrs. Bruce Richmond express assent to the report with the exception of certain recommendations concerning the Central Midwives Board. The points in which they dissociate themselves concern those recommendations that involve the splitting up of the functions hitherto assigned to the Midwives Board and their distribution between a reduced Board, the Ministry of Health, and an advisory committee. In their opinion the suggested changes are in no way essential to the midwifery service outlined in the report, and, if carried into effect, would be detrimental. The reasons which have led Dr. Fairbairn and Mrs. Richmond to make these reservations are set out on pp. 84 to 88 of the report. Their arguments are closely reasoned, and should be consulted. Among the points they make is that no evidence to justify the drastic changes contemplated was put before the committee. The proposal to effect them was submitted by the London County Council at a late stage, and there was no opportunity of testing the suggestions by reference to the bodies most affected by the proposed changes. Dr. Fairbairn and Mrs. Richmond would have welcomed a recommendation that the Central Midwives Board should exercise a wider and more general inspection than it has done, especially if poor-law institutions were included, and would have preferred the employment by the Board to a further degree of obstetric teachers of recognised standing, rather than the institution of a whole-time inspectorate.

"Dual inspection" appears to them to be a bogy that loses its terrors when closely examined. Not only do the reasons set out in the report fail to convince them of any advantage to be gained by the transference of the powers of approval to the Minister of Health, but the experience of the Central Midwives Board has shown that a similar transference in the past proved unsatisfactory and was given up. Training in all poor-law hospitals was removed from the purview of the Midwives Board at an early stage in its history. When the supervision of poor-law institutions was resumed by the Midwives Board in 1924, a large number were struck off the approved list because they were wholly unfitted to be training schools, and fell far short of the standard required of non-poor-law institutions.

In view of the considerable number of municipal and other maternity hospitals under the local health authorities—a number to be vastly increased shortly—and in view of the close relationship of the Ministry to these authorities, Dr. Fairbairn and Mrs. Richmond urge that an outside and independent body like the Midwives Board should have the decision as to their efficiency as training schools. They hold that this proposal to break up work that has been welded into a compact whole, and the distribution of its parts between an attenuated Midwives Board and a department of the Ministry of Health, with an advisory committee at its back, makes a dual control that is not likely to draw women into a profession already groaning under a weight of official supervision.

The midwives should have control over their profession at least equivalent to that exercised by registered nurses over theirs; a gradual increase in the elected representatives should be the aim, so that both, with some outside help from the medical profession and others, may ultimately be able, as other professions are, to determine conditions of training and entry and to maintain their own professional standards.

ROYAL WATERLOO HOSPITAL.—For the convenience of women and girls employed during the day, this hospital for children and women, in Waterloo-road, S.E., will from Oct. 2nd open its out-patient department every Wednesday evening.

BURY INFIRMARY.—Prof. A. H. Burgess, on Sept. 21st, opened an extension of the Bury Infirmary. This year it celebrates its centenary, having been founded in 1829 as a dispensary for the care of the "sick and injured poor." A bequest of about £66,000 from the estate of Colonel John C. Barlow has made extension of buildings and equipment possible. A sum of £30,000 is still required for endowment, and of this £17,000 has already been raised. Besides ordinary beds, 11 private nursing rooms in which patients of limited means can be accommodated and treated have been provided. These rooms are all provided with a light signalling device, which replaces the bell. The charge for these rooms is 6 guineas a week. There is also a ward with 10 beds for maternity cases. The new general ward for women has 22 beds. The extensions have increased the beds from 123 to 170, and a corresponding addition is required for the nursing staff, to be met by a new nurses' home for about 60 nurses.

THE FOSSIL MAN OF PEKING.

By Sir ARTHUR KEITH, M.D., F.R.S.,
CONSERVATOR OF THE HUNTERIAN MUSEUM OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

IT is possible that many readers of THE LANCET may be in two minds as to the most recent addition to the Gallery of Ancient Man: is "Peking Man" a genuine antique or is it, as has so often happened before, merely a cobwebbed modern replica?

Thanks to the generosity of Prof. Davidson Black, of Peking Union Medical College, I have had exceptional opportunities not only of following the steps which led to the discovery of Peking Man, but also of examining all the documents relating to his authority, and I can assure my readers that they may take Prof. Davidson Black's announcement at its full face value. Without doubt the portrait just discovered is one of the most valuable ever added to the portrait gallery of our fossil ancestry. It takes a place with four others — Pithecanthropus, discovered in Java; Piltdown Man (Eoanthropus), discovered in England; Heidelberg Man (Palæoanthropus), discovered in Germany; and Rhodesian Man, discovered in Africa. In one sense it is more important than any of those just named, because Peking Man reveals affinities to modern (neanthropic) man more than the others do, and has a better claim than they have to a place on the evolutionary line of descent which has culminated in man of the modern type.

A Genuine Antique.

That we have obtained a "genuine antique" there can be no doubt: the age at which Peking Man lived was fixed before his actual remains were found; the cave deposits in which his bones lay contain an abundance of fossil animal bones; these date the cave strata as early pleistocene, which on the most moderate of reckonings indicate an antiquity of at least a quarter of million years. Of true mankind at this stage of the world's history we had obtained but two glimpses—both in Western Europe. It is true we had a revelation of very ancient humanity in Java, but the early history of man in that vast region of the old world, which stretches from Western Europe to the furthest end of Asia, remained buried in darkness until Prof. Davidson Black made his first announcement in 1927. We now know what sort of beings lived in distant Asia in early pleistocene time. The characters of this ancient fossil form suggest that it is in Asia we are to find the evolutionary cradle of the European type. We have long wondered where the Cromagnons and other neanthropic peoples who invaded Europe and extinguished its Neanderthal natives came from. The Peking discovery points to Asia as the homeland of our palæolithic ancestors.

Let me outline the course of events which led up to the discovery of the Peking Man—Sinanthropus he has been happily named by Prof. Davidson Black. So long ago as 1903, Prof. Max Schlosser described a fossil tooth from Peking; he could not make up his mind whether it was that of a man or of an anthropoid—so blended in it were both sets of characters. This tooth was part of the stock of a Chinese apothecary, and would have, in the ordinary course of events, been ground to form medicine. In China they unwittingly consume the bones of pleistocene ancestors as medicine; in England we sometimes use them as road metal! Prof. Schlosser's publication simply drew attention to China as a possible home of ancient man; nothing more. The next step was taken in 1920. In that year Dr. J. G. Andersson, a Swedish geologist attached to the Government Survey of China, found himself among the hills to the south-west of Peking, and there at a place named Chou Kou Tien—only 25 miles from the capital—he observed an extensive cave deposit rich in animal remains. He wished to discover the nature and age of the contained fauna. An extensive collection of fossil bones was made, and early in 1926 Dr. O. Zdansky, a German palæontologist, was sent to Sweden with the collection to examine and identify its various fossil items in the laboratory of Prof. Wiman, of Upsala. While so engaged, in the summer of 1926, Dr. Zdansky came across two fossil human teeth—a lower premolar, an upper third (wisdom) molar. When news of Dr. Zdansky's discovery reached Peking, the Geological Survey of China, under an enlightened directorate, and the Peking Union Medical College, under the enthusiastic leadership of Prof. Davidson Black and the financial backing of the Rockefeller Foundation, placed an exploring company in the field early in the summer of 1927. A season's exploration ended on Oct. 16th, by Dr. Burger Bohlin finding, in the matrix of the deposit, a hard travertine rock—the unworn crown of a lower molar tooth—that of a child aged about seven years.

Characters of a New Genus.

That small specimen was all that was found of the ancient cave-dwellers during the first season's exploration. For Prof. Davidson Black it was sufficient. Those who know teeth recognise in them what ordinary men find in a human face—a multiplicity of features which provide sure guidance to racial identification. Prof. Davidson Black found features on this isolated unworn molar which had never before been seen in the molars of men, ancient or modern. Anthropoid and human features were blended; on the strength of this one tooth he created a new genus of humanity, naming it Sinanthropus, the local Peking representative becoming *Sinanthropus pekinensis.*

To those unfamiliar with dental anatomy this precipitate act of christening may seem both audacious and premature. But the anatomist's sagacity was justified by subsequent events. In the summer of 1928 an expedition again took the field, and an arduous season's work was crowned by the discovery of the following fossil parts: (1) Several large fragments of the cranial wall; these proved that Sinanthropus, like Piltdown Man, had already attained a human size of brain—a brain as large as is given to the lower living races of mankind. In the words of Prof. Davidson Black, "Sinanthropus was a large-brained form." (2) Almost the whole of the right body of a lower jaw—all save the part which supports the lower incisors. (3) The greater part of the lower jaw—including the chin region—of a child aged 7 or 8 years. (3) About 24 isolated teeth.

In the Direct Line of Human Descent.

Many of these fossil parts have still to be extracted from the rock-matrix, but enough has been exposed to justify all the inferences drawn by the anatomist from the single molar. In their actual dimensions and in their arrangement in the jaw, the teeth of Sinanthropus are not materially different from those of an Australian aborigine. The total molar length is 34 mm.—an extent often reached in the dental series of living races. The canine teeth are in no wise ape-like, as were those of Piltdown Man; as in the Heidelberg jaw, they have sunk to the level of their neighbours. Yet in the molar teeth simian features are apparent; some are also to be seen in the details of structure of the cusps and crown. A minute study of the cusps reveals to my eye certain changes which in their nature are identical with those to be observed in the molar teeth of neanthropic man. In spite of their simian features and individual peculiarities the molars of Sinanthropus make a nearer approach to those of modern man than do the teeth of any of other ancient type.

The bony framework of the lower jaw reveals stages in the passage from an anthropoid to a human form. The simian shelf is disappearing; the first rudiment of the true chin has appeared. We see the separation and differentiation of the two elements of the lower jaw—the alveolar element, which is concerned in the support of the teeth, and the basal bony framework, which supports the alveolar bone and gives attachment to muscles. In the ape the alveolar bone predominates and masks the basal element; in modern man the alveolar element has become reduced, thus exposing the enlarged basal framework on which the shelf of the chin is set. In the crudely fashioned mandible of Sinanthropus we have a transitional stage—one in which basal framework and chin are attaining a separate differentiation. The dental canal of Sinanthropus is altogether remarkable; it is very wide, particularly in front, and its walls are clearly differentiated as in the mandibles of anthropoids and as in that of Piltdown Man. As usually occurs in the lower jaw of anthropoid apes, the mental nerves escape by four foramina.

One Outstanding Feature.

Altogether the characters of Sinanthropus are such as we expect to find in an ancestral stage in the evolution of modern man. Only one feature makes me hesitate in placing him on the line of our ancestry. That is the large size of the pulp cavities of the molar teeth. Sinanthropus shows a considerable degree of that enlargement of the body of the molar teeth and of the contained pulp, known as taurodontism—about the same degree as is seen in the ancestral stage of Neanderthal man revealed by the Heidelberg jaw. Taurodontism reached its climax in the later forms of Neanderthal man. The molar teeth of modern man are not taurodont; they are the opposite; like those of anthropoid apes, they are "cynodont." The bodies of the teeth of modern man are low, and the pulp cavities are shallow. Prof. Davidson Black recognises the taurodont nature of the sinanthropic molars, and inclines to the opinion that taurodontism is a mark of early humanity. I cannot share this opinion; to me taurodontism is a form of dental degeneration. I cannot conceive that once this taurodont change had set in the process could have been reversed and cynodontism regained. Hence my difficulty regarding the position of Sinanthropus in the human family tree. I would place him right in a central position at the base of the branch which has given birth to modern races were it not for this feature of his molar teeth. If he is not to be given a position in the direct line of our descent, we must, to account for such characters as we now know he possessed, at least place him at the pleistocene root of the modern branch, and very nearly on the direct line of neanthropic descent.

The Peking discovery reflects credit on all concerned—on Prof. Davidson Black, Dr. J. G. Andersson, Dr. O. Zdansky, and Dr. B. Bohlin. Especially must we recognise the enlightened enthusiasm which brought to their aid the Geological Survey of China, the Peking Union Medical College, and the Rockefeller Foundation.

DONATIONS AND BEQUESTS.—Mr. J. R. Macfie, Glasgow, left £500 each to the Royal Cancer Hospital, and the Association for the Relief of Incurables in Glasgow and the West of Scotland.—Among other bequests the late Dame Edith Jane Durning-Lawrence left her library ultimately to the University of London and £10,000 to University College, with the request that this bequest should be applied in connexion with the equipment of the Physical and Electrical Chemistry Laboratory at that College, but if such be already completed, then for the endowment fund, of which the income should be used in connexion with research in medical sciences in the said College and its research laboratories; £10,000 to the University of London for the endowment of a professorship or chair at University College for the teaching of medicine according to the principles laid down by Hahnemann, the first occupant of such chair to be Dr. John Weir, if he should be willing to accept such office. If, however, the University does not accept this bequest, it is to revert to the British Homœopathic Association (Incorporated); £10,000 to the Victoria University, Manchester, for a John Benjamin Smith Fund as a memorial of her late father; £10,000 to the University of Liverpool for a Durning-Lawrence Memorial; £8000 to the London Homœopathic Hospital, Great Ormond-street, W.C.; £5000 each to the London Hospital and King Edward's Hospital Fund for London; £4000 to the Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.; £1000 to King Edward VII. Hospital, Windsor; and £200 to the Royal Victoria Nursing Home, South Ascot.

THE MEDICAL REGISTER: UNTRACEABLE PRACTITIONERS IN 1929.

WE are requested by the Registrar of the General Medical Council to publish the following list of medical practitioners who have not replied to his inquiries as to the accuracy of their addresses. Anyone, wherever resident, who finds his or her name included in this list should communicate immediately with the Registrar of the General Medical Council, 44, Hallam-street, Portland-place, London, W. 1, otherwise the name will be omitted from the next issue of the Medical Register. There may be some who have answered while this list is in the press. Those marked "(S)" should communicate direct with the Registrar of the Scottish Branch Council, 12, Queen-street, Edinburgh.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Comdr. W. P. Hingston is placed on the Retd. List with rank of Surg. Capt.

Surg. Capt. R. W. G. Stewart is placed on the Retd. List.

S. Jenkinson and N. J. U. Mather to be Surg. Lts.

The following appointments are notified: Surg. Lt.-Comdr. (D.) C. Williams to *Pembroke*, for R.N. Barracks, Chatham; Surg. Lts. E. E. Malone and G. A. Miller transferred to Permanent List.

ROYAL NAVAL VOLUNTEER RESERVE.

Surg.-Comdr. T. B. Dixon is appointed Admiralty Surgeon and Agent for Bristol.

ROYAL ARMY MEDICAL CORPS.

Maj.-Gen. H. B. Fawcus to be Lt.-Gen., and to be Dir.-Gen., Army Med. Services, War Office.

Lt.-Gen. Sir M. H. G. Fell retires on ret. pay.

Maj.-Gen. Sir A. P. Blenkinsop, retd. pay, is apptd. Col. Comdt., vice Maj.-Gen. Sir M. W. O'Keeffe.

Col. W. R. Blackwell to be Maj.-Gen., vice Maj.-Gen. H. B. Fawcus.

Maj. F. C. Atkinson-Fleming is placed on the half-pay list on account of ill-health.

Capt. H. G. P. Armitage to be Maj.

ROYAL AIR FORCE.

Flight Lt. J. Hill is granted a permanent commission in this rank.

Flying Officer G. T. O'Brien is promoted to the rank of Flight Lt.

Squadron Leader J. H. Peck relinquishes his short service commission on account of ill-health and is permitted to retain his rank.

INDIAN MEDICAL SERVICE.

Maj. S. Gordon retires.

Capt. Bodh Raj Chaudhri to be Maj.

Temp. Capt. Bhalchandra Kondopant Phatak and Temp. Lt. Jaswant Singh Anand relinquish their temp. commns.

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

THE following are some 1928 statistics of six administrative counties :—

Name of district and estimated (R.-G.) population.	Birth-rate.	Death-rates per 1000 of the population.					Death-rates per 1000 births.		
		All causes.	Tuberculosis.	Cancer.	Respiratory diseases with influenza.	Heart disease.	Infant and neonatal mortality.	Young child (1–5 yr.) mortality.	Maternal mortality from childbirth.
Surrey .. .. (841,090)	14·2	10·2	0·66	1·53	1·2	1·7	47	21	4·0
Wiltshire .. (301,200)	15·7	10·8	0·61	1·61	1·1*	2·0	46	—	3·0
Norfolk .. (322,300)	16·4	12·1	0·73	1·76	1·2	2·0	56	17	2·8
Leicestershire (291,800)	17·4	10·5	0·88	1·21	1·2	1·7	55	19	4·7
Northamptonshire (215,170)	14·7	11·6	0·8	1·6	1·4	2·2	48	16	5·6
Holland .. (88,860)	20·6	11·2	0·71	1·56	1·4	1·5	46	19	4·4

* " Other respiratory diseases " not included.
— = Figure not available.

Surrey.

Dr. Andrew Davidson (deputy) presents the report and mentions as a notable feature the opening of the county sanatorium at Milford. On several occasions during 1928 the Surrey tuberculous patients in various hospitals and sanatoriums exceeded 400 in number. The new sanatorium accommodates 300, with two 50-bed pavilions for advanced and four 50-bed pavilions for intermediate and early cases. The site covers 110 acres in healthy open surroundings in the Guildford and Hambledon rural districts about 230 ft. above sea-level with a gentle slope to the south. The sanatorium was opened by the Minister of Health on July 20th, 1928. Over 200 patients were admitted during 1928, and by May, 1929, the institution was full. There were two outbreaks of small-pox—one in January of seven cases and a second in April of 22 cases. In both instances the infection appears to have been introduced by tramps. During the third quarter there was an outbreak of paratyphoid B, chiefly localised in the Epsom neighbourhood. The outbreak was synchronous with that which occurred in Kensington, and the M.O.H. of Carshalton and Epsom considered the probable source of infection was the cream-supply to which the London cases were traced.

The sum paid by the county council to doctors called in by midwives amounted to £1235 16*s*. 9*d*., of which £335 16*s*. was afterwards recovered from the patients. There were 169 notifications of puerperal fever and pyrexia, and 17 of the patients were admitted to hospital. The county council subsidises various maternity homes to which patients seen at the ante-natal clinics by an assistant county medical officer are admitted. During 1924 54 such patients were admitted, and this number has increased year by year to 219 in 1928. In addition to this the number of expectant mothers visited by the council's health visitors was 974, the total births in the administrative county being 11,911. A scheme for the dental treatment of expectant and nursing mothers will be in full operation in 1929. The children under 5 who received treatment for crippling defects at the five orthopædic centres in the county numbered 239. The number of new V.D. cases from Surrey dealt with under the London scheme was 773, and for the accommodation of patients in the more remote parts of the county V.D. clinics are in existence at Guildford and Redhill, and it is hoped that the clinic at the Royal Hospital, Richmond, will be re-established during 1929.

At the beginning of the year the county council had appointed a chief veterinary officer to deal with milk control and the Diseases of Animals Acts, and in March three full-time assistant veterinary surgeons were appointed. The number of the part-time veterinary staff has been reduced from eight to seven. In 15 instances complaints of tuberculous milk were received from outside sources. In one case the milk, though sent out from a Surrey dairy, was entirely produced in another county. Of the remaining 14 cases, 12 of the infected samples came from one farm, 1 from two farms, and 1 from three farms. In 7 of the 14 cases one or more cows were found suffering from tuberculosis and slaughtered. The veterinary staff carry out a quarterly inspection of the herds, which comprise nearly 15,000 cows in milk. Among the cows in milk they found in 1928 147 suffering from tuberculosis, of which 45 had tuberculosis of the udder.

At the end of 1928 711 blind persons were on the register, of whom 225 were employed and 402 unemployable. The county council augments the wages of blind home workers through the National Institute to the extent of 5*s*. per week, the total sum paid under this heading being £502 0*s*. 10*d*. It is considered that the provision of free wireless licences and the regular supply of Braille and Moon literature and music increases the readiness of blind persons to register under the Act.

Wiltshire.

Dr. Claude E. Tangye mentions that the staff has been strengthened by the appointment in August of Dr. J. B. Lowe as deputy M.O.H., and that his time has largely been occupied with the small-pox outbreak in the Swindon neighbourhood, which still continues (April, 1929). A deficiency in the tuberculosis scheme mentioned in the last report has been met by the appointment of Dr. P. St.J. Wilkinson as tuberculosis officer for the Swindon area, for which he already acts as V.D. medical officer. The county is well provided with isolation hospitals, but with modern ambulance facilities the number of these could be reduced with advantage. In spite of local opposition a ministerial inquiry was held early in 1929 with regard to a new water-supply for Ashton Keynes. The existing wells are polluted and are held responsible for the infection of the school-children by intestinal worms. The water-supply of Long Newnton has apparently caused cases of paratyphoid fever in that parish. A chlorination plant has been installed with satisfactory results, but the rural district council is being urged to provide a satisfactory permanent new supply. The analysts' reports on 34 sewage effluents showed 18 good results, five bad, and the remainder intermediate. Up to March 31st, 1929, financial assistance amounting to £3209 had been promised by the county council in respect of 37 premises under the Housing (Rural Workers) Act, 1926. At the same date £1319 had been paid for work completed at 14 dwellings, and in ten other instances the work was in hand.

The outside complaints of tuberculous milk numbered 15. In three instances the milk was consigned to London in bulk from large collecting depôts in the county, and in view of the large numbers of farms involved complete veterinary inspection was found to be impracticable. The remedy appears to be continuous sampling at the depôts of the produce of individual farms. The following-up of the remaining 12 infected samples resulted in the discovery of tuberculous cows in the case of 10 of the 12 herds inspected. Dr. Tangye expresses doubt as to the value of inspecting herds when the guinea-pigs die from acute infections other than tuberculosis. The work involved is considerable, and it frequently happens that nothing definite is discovered at the farm to account for the deaths of the guinea-pigs.

The county council pay midwifery subsidies to 81 nursing associations, and in two cases subsidies to individual midwives to enable them to attend cases in isolated parishes. Most of the midwives now possess pelvimeters for antenatal work supplied at reduced price through the county council. The county council paid £703 in midwifery fees to doctors and recovered £306 from the patients. The county orthopædic scheme, based on the Bath Hospital and with five out-clinics, is working successfully, and dealt with 1049 new cases as compared with 873 in the previous year. The scheme is being extended by the institution of remedial exercise classes at the schools in order to provide early corrective treatment for defects of posture. The education committee also has under consideration a comprehensive plan for the occupational training of cripples.

Norfolk.

Dr. T. Ruddock-West, who only took over his duties on June 1st, mentions that before the close of the year he had held conferences with the various district medical officers of health in order to discuss the needs of the county. Isolation hospital accommodation is inadequate, and a central hospital is indicated as the best means of serving unprovided areas. There were 42 cases of small-pox notified with two deaths. Forty-one of the cases occurred in the borough of King's Lynn. The county council is responsible for maternity and child welfare work for the administrative county, with the exception of King's Lynn, Swaffham U.D., and Forehoe R.D., and Dr. Ruddock-West thinks the notification of births should be made direct to the county M.O.H. In 105 of the 690 parishes no provision has yet been made for infant health visiting. There are seven child welfare centres established by the British Red Cross Society, which receive subsidies from the county council. There are, in addition, a number of smaller unsubsidised centres established by voluntary agencies, such as local nursing associations. Antenatal clinics are indicated as one of the needs. Eight outside complaints of tuberculous milk were received and investigated by the (part-time) veterinary officer. As a result six cows were slaughtered under the Tuberculosis Order. As the result of an adverse report by the Fishmongers' Company with regard to Hunstanton mussels marketed in London, samples of mussels, water, and mud were taken on Nov. 30th and examined in the county laboratory. The mussels proved to be 70 per cent. clean, and certain suggestions were made with regard to the discharge of sewage. Further samples of mussels examined by the Fishmongers' Company were found to be clean.

Leicestershire.

Dr. J. A. Fairer says that the total estimated increase of the county population during the last two years—viz., 12,100—is largely due to the migration of city dwellers to houses recently built in the surrounding districts. The recovery of the mining district in the north-west, after the coal stoppage of 1926, is slow and uncertain, and unemployment and distress are reflected in defective nutrition among the children. In the industrial district of the south-west the absence of the mother from her home does not apparently affect the children, and the infant mortality-rate for Hinckley was only 30·5 per 1000 births. Maternity and child welfare work was originated in the county by voluntary societies, and with a view to obtaining better medical supervision Dr. Constance Walters was appointed county medical officer for infant welfare during the year. There are now 30 centres under the administrative control of the council. Antenatal supervision is chiefly carried out by the county health visitors. There are a considerable number of hospitals and clinics at which orthopædic work is done, but up to now it has not been possible to institute a coördinating scheme by which a continuous and accurate record of each child will be kept. The county council has appointed Dr. J. M. Mackintosh to conduct the investigation into maternal deaths required by the Ministry. Dr. E. L. Lilley has repeated his successful series of lectures to the county midwives. The county council subsidises nursing associations for midwifery services in six sparsely populated areas. The midwifery fees paid to doctors totalled £314 2*s*., of which £175 16*s*. was recovered from the patients.

Dr. Fairer reports a considerable improvement in the condition of nearly all the sewage farms adversely reported upon last year. Grants were made amounting to £1015 in respect of 13 dwellings under the Housing (Rural Workers) Act, 1926. The outside complaints of tuberculous milk numbered 13. As a result 277 cows were inspected, the milk of 83 individual cows was examined bacteriologically, and seven cows were dealt with under the Order. The informal bacteriological examination of milk is apparently improving the standard of cleanliness; thus the percentage of "good" samples during the last three years has been 40·7, 47·1, and 58·8. The plans for the proposed new county sanatorium are nearing completion.

Mild small-pox made its appearance at the close of 1927, and during 1928 there were 25 cases, the last notified on Nov. 24th, with no deaths. There were 18 cases of ophthalmia neonatorum, in two of which vision was impaired.

Northamptonshire.

Dr. L. Meredith Davies records the occurrence of 20 cases of small-pox, chiefly among tramps. There were epidemics of diphtheria in Desborough U.D. and Crick R.D., and the county medical staff gave assistance in both cases in the tracing of contacts and the detection of carriers. A worker in a tannery contracted anthrax. The pustule was excised and he was also treated with Sclavo's serum and made a good recovery. There were 17 notifications of puerperal fever with four deaths. All the cases except one were sent into hospital and a special nurse was provided in one case before removal. There were 30 notifications of puerperal pyrexia, and no request for a special nurse was received for the 23 cases occurring in districts other than Kettering U.D. Four hospitals have been made available for the treatment of women suffering from these diseases. There were 21 notifications of ophthalmia neonatorum, and in one case both eyes were damaged. Arrangements have been made with three hospitals for the admission of both mother and baby and also for the supply of a special nurse. The county council make grants to three isolation hospitals, at Daventry, Kettering, and Oundle. Daventry Hospital has many needs. It has no trained nursing staff, no ambulance, and a very old type of disinfector. Kettering Joint Hospital has just been extended and improved. Oundle Joint Hospital treats so few cases (viz., 15 in 1926, 8 in 1927, and 1 case of small-pox for the first six months of 1928) that Dr. Davies considers its continuance is unjustifiable and that the board should unite with another district.

A scheme for tuberculosis care committees has been approved and will come into operation on April 1st, 1929. There will be one representative central committee and six area committees. Marked benefit is reported from light treatment for suppurating tuberculous glands and less notable benefit in glands without suppuration and lupus. The county council financed the admission of one patient to Papworth Colony. The claims received from medical practitioners called in by midwives numbered 113; the payments made amounted to £167, of which £51 was recovered from patients. Under the heading "Rivers Pollution" Dr. Davies gives extracts from the reports made on the conditions found at many sewage farms. The result may be summarised as "bad" in 21 cases, "good" in 4, and "intermediate" in 14. The investigation of six outside complaints of tuberculous milk resulted in the discovery of one tuberculous cow only. From Feb. 1st for 18 months an inspection of dairy cattle twice in each year by (part-time) veterinary surgeons came into force. As a result 29 tuberculous cows were found, including those with the udder affected. The veterinary surgeons are also appointed sanitary inspectors, and thus empowered to deal with unsatisfactory conditions found on the farms.

Holland.

Dr. H. C. Jennings reports that the work done in the county laboratory has been of great benefit, but would be of much wider service if a trained assistant were appointed. There were 26 cases of small-pox with no deaths. In 12 of the cases in Spalding infection was traced to a tramp. There were 12 notifications of ophthalmia with one case of impaired vision removed from hospital against medical advice. There were 52 deaths from pneumonia, and Dr. Jennings would like to have hospital treatment for all pneumonia cases. Two cases of encephalitis were notified and both died. The tuberculosis mortality was the lowest ever recorded; 355 new cases were reported and 184 contacts were examined. The 30 shelters available in the county were used by 46 patients during the year. More local nursing associations are needed to ensure adequate attention to mothers in childbirth. As it is, the problem of the "handywoman" is an ever-present one. The amount paid in fees to practitioners called in by midwives was £88 18s., of which £9 5s. was recovered from patients. The public analyst reports a sample of egg powder as "inferior." It consisted of starchy matter and a small amount of baking powder, and was coloured with an aniline dye. There is, however, no accepted definition or standard for egg powder. Under the Tuberculosis Order 86 animals were slaughtered, four of which were cows in milk with tuberculosis of the udder. Several of the districts in the south of the county have unsatisfactory water-supplies and are in negotiation with the Spalding U.D.C., which own bores at Bourne, from which an ample supply of pure water is obtained. In an appendix on the isolation hospital accommodation of Holland Dr. Jennings indicates that the ideal would be to erect one hospital in a central situation to serve the whole county. Unfortunately, the lack of a piped water-supply in the greater part of the area very much limits the choice of suitable sites.

MENTAL HOSPITAL REPORTS.

THE *Devon Mental Hospital* issues this year its eighty-third annual report, illustrated by two photographs, one of the ballroom and the other of the female private ward, made gay by a veritable herbaceous border of hand-made floral decorations. There were 1333 patients on the register on Dec. 31st, 1928, an increase of 110 during the year, so that on the female side the hospital is now overcrowded and in urgent need of extension. The increase in the admission-rate is largely due to the reception of patients on contract from Staffordshire, Birmingham, and Plymouth. These were chronic cases, yet the recovery-rate for the year reached 37·82 per cent. The death-rate was 7·6 per cent., and autopsies were held in all cases where permission could be obtained—72·34 per cent. The number of cases of pulmonary tuberculosis has been reduced by improved diet, and by ultra-violet ray and sanatorium treatment. In the autumn there were three cases of dysentery, but there has been no typhoid since the routine inoculation of all patients with "TAB" was instituted. The laboratory carried out a large number of routine and special examinations; the dentist visited fortnightly and examined 636 patients, and the visiting ophthalmic surgeon made 76 examinations. The visiting surgeon paid 40 visits, saw 107 cases, and performed 29 major operations. The visiting radiologist made 59 investigations, and 35 patients were treated in the light department. During the year 13 men and 2 women suffering from general paralysis were treated by malaria, 7 by mosquitoes, and 8 by direct inoculation of malarial blood. Three of the patients were sent home, 4 showed no appreciable change, and 4 died. In future, arsenical preparations are to be given as well as malaria, and the results will be compared with those following malarial treatment alone. Parole within the estate was granted to 80 patients; 46 were allowed outside and 55 were taken out by friends. As far as possible the open-door system is adopted. Char-à-banc picnics were enjoyed by 518 patients, and daffodil, primrose, and blackberry-picking parties were organised. The sum of £170 was raised at the annual patients' sports. The method, devised by the engineer, whereby the wireless can be transmitted through the telephone system, continues to work satisfactorily, and there is a portable set for wards not supplied with a telephone. The library has been completely reorganised in a central room, and the weekly illustrated papers are now circulated in folios made in the bookbinding department of the printers' shop. Bookbinding occupies two patients, weaving five, net-making three, and mat-making two. The brush- and basket-making department, served by eight patients, has turned out excellent work, and knitting, rug-making, and raffia occupy some of the women. In all, 271 patients have useful employment. At the out-patient clinic there were 63 attendances, nearly twice as many as in 1927. A new sterilising room was added to the operating theatre, and two new cottages were built for the male nursing staff. One nurse passed the final examination of the General Nursing Council, and 12 nurses and two attendants obtained their R.M.P.A. certificate.

The *Roxburgh, Berwick, and Selkirk District Asylum* had 368 patients, including four voluntary boarders, in residence on May 15th, 1929. The recovery-rate was 35·2 per cent. and the death-rate 7·9 per cent. Cause of death was verified by autopsy in 17 cases. During the year the hospital was fortunate in admitting more recoverable and fewer senile cases than usual. Apart from a sharp epidemic of influenza the health was excellent. The dental surgeons visited every fortnight. An occupational therapy class has been started, and a kinematograph apparatus has been installed. Thirteen members of the staff sat for the R.M.P.A. examination, and all but one were successful.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED SEPT. 14TH, 1929.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 96 (last week, 150); scarlet fever, 2015, diphtheria, 1100; enteric fever, 113; pneumonia, 500; puerperal fever, 50; puerperal pyrexia, 90; cerebro-spinal fever, 13; acute poliomyelitis, 12; acute polio-encephalitis, 3; encephalitis lethargica, 14; continued fever, 1; dysentery, 4; ophthalmia neonatorum, 119. No case of cholera, plague or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on Sept. 17th–18th was as follows:—Small-pox, 121 under treatment, 16 under observation (last week 156 and 14 respectively); scarlet fever, 1417; diphtheria, 1524; enteric fever, 21; measles, 243; whooping-cough, 209; puerperal fever, 23 (plus 6 babies); encephalitis lethargica, 125; poliomyelitis, 3; "other diseases," 25. At St. Margaret's Hospital there were 22 babies (plus 10 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 3 (3) from enteric fever, 9 (2) from measles, 2 (0) from scarlet fever, 27 (4) from whooping-cough, 24 (2) from diphtheria, 103 (17) from diarrhœa and enteritis under two years, and 22 (2) from influenza. The figures in parentheses are those for London itself.

Of the deaths from diarrhœa (which have increased by one-third), 8 were reported from Liverpool, 7 from Gateshead, 6 from South Shields, 5 each from Birmingham, Hull, and Middlesbrough, 4 from Leeds; while Glasgow, Dublin, and Belfast, reported 7, 5, and 5 respectively. Two deaths from measles were reported from Stoke-on-Trent.

The number of stillbirths notified during the week was 205 (corresponding to a rate of 42 per thousand *births*), including 40 in London.

Correspondence.

"Audi alteram partem."

THE RELATION OF THE TONSILS TO RHEUMATIC CONDITIONS.

To the Editor of THE LANCET.

SIR,—The suggestive paper by Dr. Gray Hill in your issue of Sept. 14th (p. 571) upon the value of tonsillectomy in acute rheumatism, rheumatic carditis, and chorea raises the important question of the true relation between the tonsils and rheumatic conditions, and makes us ask ourselves whether we are not pursuing a chimera, and that it is necessary to pause and reconsider carefully the position. The tabulated cases upon which Dr. Hill's contention is based seem clearly to demonstrate that tonsillectomy, even when efficiently performed, has no influence upon the behaviour of rheumatism and is no safeguard against carditis or chorea, an opinion which supports those of Poynton, Vining, Hunt, Osman, MacSweeney, Boas, Schwartz, and Wilson as against the too enthusiastic assertions of Schichhold, Robey, Freedman, Kerby, Miller, and Thomson.

I think that many practitioners of experience will endorse me when I say that, apart from a certain general improvement that must necessarily accrue from the removal of a definitely septic focus, tonsillectomy has no influence upon the incidence or course of any rheumatic condition, either acute or chronic. This being so, it behoves us to look further afield, and to search for a more likely reason for the undoubtedly frequent concurrence of septic tonsils in rheumatic cases, and one which will also give us more certain indications for treatment. The first suggestion that occurs is that the rheumatic condition is not dependent upon the tonsil sepsis, but that both are in fact the result of a source of infection situated elsewhere.

I personally believe that the most frequent source of rheumatism, septic tonsils and septic teeth, lies in the chronic toxæmia which results from chronic intestinal intoxication. Research should lie in the direction of establishing a possible connexion between rheumatic conditions, or septic tonsils, or both, and the various pathogenic organisms occurring in intestinal toxæmia. Such a connexion would tend to give indications for prophylaxis and rational treatment.

I am, Sir, yours faithfully,

MACLEOD YEARSLEY.

Wimpole-street, W., Sept. 19th, 1929.

DISPLACEMENT OF THE MANDIBULAR CARTILAGE.

To the Editor of THE LANCET.

SIR,—I have long been interested in the subject of the displacement of the mandibular cartilage discussed by Mr. Wakeley in your columns on Sept. 14th. I had to do with two patients of the late Prof. Annandale who was the first surgeon to treat recurring displacement of this meniscus by operation, as he was the first to operate for "displaced semilunar cartilage" of the knee-joint. A more intimate reason for my interest in this unusual accident was my personal experience of the extreme discomfort it can cause. I found a method by which I could reduce the displacement by manipulation. Ten years ago I contributed to the *British Journal of Surgery* (1919, vi., 385) an article designed (1) to make clear that the description of the meniscus in our anatomical text-books was not a correct one; (2) to indicate by original diagrams what I believed to be the characteristic shape and appearance of this structure; (3) to describe the sensations and symptoms which result from a recent displacement and how I conceived them to be brought about, as well as to describe my method of reduction by manipulation; (4) to record a case of constantly recurring displacement which I treated in 1911 by excising the meniscus. Mr. Wakeley's account of the condition does not appear to differ in any particular respect from my own, and it is gratifying to observe that the method which he describes as being "the best method of reduction" is that recommended by me. It is unusual to find one's statements on a subject in surgery so completely corroborated in every detail as mine have been by Mr. Wakeley without a reference to the original descriptions, especially when an accident is uncommon and has received scanty attention in the literature. However, since THE LANCET is extensively read by practitioners who may not see the more specialised journals regularly, it is all to the good that attention should be called to the condition in your columns.—I am, Sir, yours faithfully,

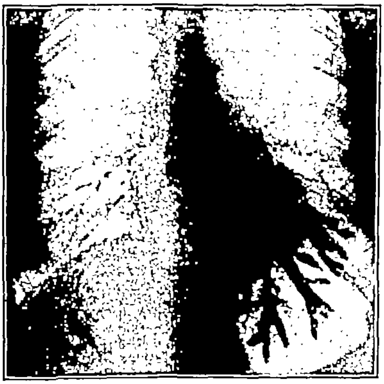
J. HOGARTH PRINGLE.

Peebles, Scotland, Sept. 16th, 1929.

RADIOGRAPHIC EXAMINATION OF THE LUNGS.

To the Editor of THE LANCET.

SIR,—On X ray examination of the lungs the bases are obscured by the domes of the diaphragm and abdominal contents. In cases of left-sided disease we give some sodium bicarbonate before the examination, in order that there may be gas in the stomach to render the bases of the lung more visible. The radiogram here reproduced shows a patient with left basal bronchiectasis and lipiodol in the dilated bronchi. It will be seen how clearly the condition shows up against the air bubble in the stomach.



Radiogram showing left basal bronchiectasis.

We are, Sir, yours faithfully,

L. S. T. BURRELL,
STANLEY MELVILLE.

Chandos-street, W., Sept. 10th, 1929.

THE AGE OF MARRIAGE AND OF CONSENT.

To the Editor of THE LANCET.

SIR,—In your leading article last week (p. 618) reference is made to the Hindu custom of early marriage. Therein is quoted a statement by Dr. Margaret Balfour and Dr. Ruth Young to the effect that this custom amongst the Hindus is founded on the principle that early marriage is likely to lead to chastity in the youth of both sexes. This statement appears to be of the nature of an *argumentum a* *posteriori*, and does not seem to be very convincing, or at least is true only to a very limited extent. Is not the explanation which the Hindus themselves put forward more reasonable and more in accordance with experience—namely, that the Muslim conquerors of India took the unmarried girls only into their harems? It thus became a question of national existence and national honour that to save the girls from this abduction they should be married at an early age. In order to bring about the general acceptance of this practice religious sanction was invoked from the ancient Sanskrit texts. It is to be remembered that early marriage was already a Muslim custom. I am, Sir, yours faithfully,

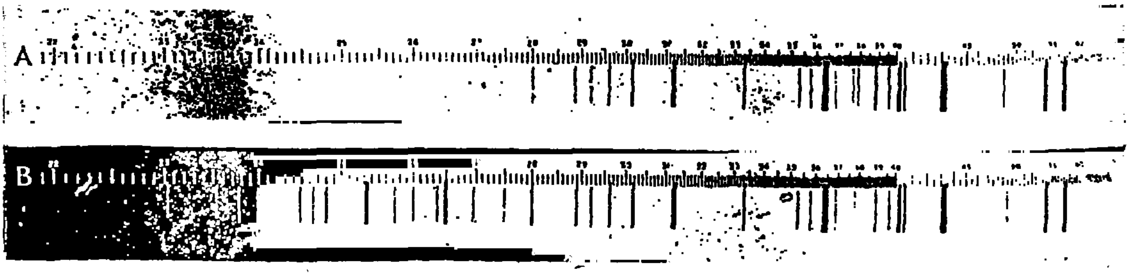
Birmingham, Sept. 23rd, 1929. G. A. AUDEN.

*** Since our article appeared the Child Marriage Bill, which provides that the age of girls at marriage shall not be less than 14 years and the age of consent not less than 16 years, has passed the Indian Legislative Assembly.—ED. L.

THE STABILISATION OF "VITA" GLASS.

To the Editor of THE LANCET.

SIR,—In an annotation entitled Special Glass in School Windows in your issue of August 24th (p. 398) it is implied that "Vita" glass tends to lose its special penetrability with time. I shall be much obliged if you will allow me to correct the erroneous impression thus conveyed. When "Vita" glass is exposed to the sun it undergoes a change, which consists of a slight diminution of the transparency to the sun's rays of the shortest wave lengths. This physical change does not in any way affect the appearance of the glass and is almost invariably complete within nine months, and often within a shorter period, after glazing. This period is called the period of stabilisation, and at the end of it no further change in transmission will take place.



Mercury-vapour lamp spectra: (A) screened by fully stabilised "Vita" glass; (B) unscreened.

The effect of stabilisation is shown by the following figures which give percentage transmission of a typical piece of "Vita" glass of 2 mm. thickness at wave length 3130 A.U.

	3130 A.U.
New "Vita" glass	72 per cent.
Stabilised "Vita" glass	64 "

The reading at 3130 A.U. is taken because this is approximately the wave length where the maximum therapeutic strength of sunlight lies, as found by Dorno. At this wave length there is a very strong line in the spectrum from a mercury-vapour lamp, enabling the determinations of percentage transmission through the glass to be done with great accuracy.

When this state of stabilisation is reached "Vita" glass still transmits to the limit of the sun's spectrum as is shown by the accompanying spectrographs made with:

(*a*) Mercury-vapour lamp unscreened.

(*b*) The same lamp screened by fully stabilised "Vita" glass.

The idea that there is serious deterioration in "Vita" glass has originated through the publications of investigators who have subjected the glass to radiation from mercury-vapour lamps, which irradiate it with wave lengths far shorter than any we ever receive from the sun. It has been proved that exposure to the mercury vapour lamp is no guide to the effect of solar radiation upon "Vita" glass. The year selected for the investigation by the Board of Education was an unfortunate one, because the readings of ultra-violet radiation for the whole of these 12 months are very much below the average, and it should not therefore be assumed that because the results were not all that one could wish for, they would not be so under normal conditions.

Some of your readers will have seen by this time actual demonstrations of "Vita" glass, which go to prove conclusively that "Vita" glass admits the health-giving rays of the solar spectrum, to which ordinary glass is opaque, and I should therefore like to emphasise that all demonstrations of this kind are carried out with glass which has been completely stabilised.—I am, Sir, yours faithfully,

R. R. BYRNE,
Director, "Vita" Glass Marketing Board.

Aldwych House, London, W.C., Sept. 13th, 1929.

*** We have independent testimony that the loss in transparency when exposed to natural sunlight—briefly called solarisation—is not as great as has been made out. The current number of *Nature* (p. 441) contains a report of investigations at the Crown Glass Works at St. Helens, which show that glass which has been solarised by exposure to the quartz mercury lamp may even regain some of its lost transparency when exposed to sunlight. In America some work at the Bureau of Standards, confirmed by Dr. G. W. Caldwell and Dr. R. H. Dennett (*Jour. Amer. Med. Assoc.*, June 22nd, p. 2088), indicates that solarisation is complete in a few weeks, after which the permeability of the glass does not change. Both papers presuppose the feasibility of keeping the surface of the glass free from deposit.—ED. L.

SCHISTOSOMA BOVIS IN SOUTH AFRICA.

To the Editor of THE LANCET.

SIR,—Eight years ago you published[1] a letter from me drawing attention to the fact that *Physopsis africana* in Natal was infested with cercariæ which developed into the adult *Schistosoma bovis*. The occurrence of ova apparently identical with those of *S. bovis* in some patients who had acquired bilharzia infection, whilst bathing in pools infested with this parasite, suggested that the schistosome occasionally would choose man as its final host. Dr. E. C. Faust, who has made an exhaustive study of South Africa's larval trematodes, regards *Cercaria octadena* as the larval stage of this schistosome and observes that the cow is not necessarily the common South African host. More recent work has shown that both oxen and sheep are infested with *S. bovis* in the Eastern Province of the Cape, and the parasite would appear to exist in the Pretoria district of the Transvaal as well as on the Natal coast.

---

[1] THE LANCET, 1921, i., 250.

Mr. P. L. Le Roux, of the Veterinary Department at Onderstepoort, who has been engaged in a valuable study of schistosomiasis in South African cattle and sheep, now tells me that he has observed that, where massive doses of tartar emetic are employed in the treatment of schistosomiasis, the parasites are soon found in a dying condition in various portions of the lungs. This interesting observation may explain why patients are so predisposed to temporary "colds," when larger doses than they can comfortably tolerate have been administered in the series. In the experiments which Dr. H. H. Curson, M.R.C.V.S., kindly undertook for me with freshly dissolved tartar emetic in the treatment of some fluke-infested sheep, he showed that antimonium potassium tartrate was a relatively non-toxic drug, if skilfully applied to sheep, as it is when administered to man.

I am, Sir, yours faithfully,
F. G. CAWSTON, M.D. Camb.,
late Streatfeild Research Scholar.

Durban, Natal, Sept. 3rd, 1929.

Obituary.

EDWARD PETRONELL MANBY, M.D., D.P.H. CAMB.

WE regret to record the death of Dr. E. P. Manby, a medical officer of the Ministry of Health, which took place suddenly on Sept. 20th at his house in London, just after the completion of his sixty-fifth year.

Edward Petronell Manby came of a medical family, his brother, the late Sir Alan Manby, being for many years physician extraordinary to His Majesty the King and surgeon-apothecary to the Royal Household at Sandringham. Edward received his training at Cambridge, where he graduated in 1883, and at Guy's Hospital, taking the conjoint qualification in 1886, the Cambridge M.B., B.C. in 1887, M.D. in 1891, and D.P.H. in 1894. Early in his professional career he became a resident medical officer at the Fountain Hospital of the Metropolitan Asylums Board, a post which he relinquished in 1896 on appointment as assistant medical officer of health at Liverpool. His work there did not pass unnoticed at Whitehall, and in 1900 he was invited to become a medical inspector to the Local Government Board; on the constitution of the Ministry of Health in 1919 he became a medical officer of that Department. From 1891 to 1900 he was lecturer in public health in the Liverpool University, and later in his career he held examinerships in public health in the Universities of London, Leeds, and Liverpool.

Dr. Manby's service with the central health authority extended over a period of nearly 30 years. He took his share in the routine inspection of the areas of local sanitary authorities and was entrusted with special inquiries of considerable importance, notably one into the conditions under which milk is distributed in this country. For the last ten years he had been engaged in the supervision of poor-law institutions in London and the home counties, and his special knowledge of this field of work was so valuable, especially in view of the changes occasioned by the Local Government Act of 1928, that his period of service was extended beyond the ordinary age of retirement. His life was, in fact, as one of his colleagues writes, devoted to public service, for which he had many qualifications, chiefly perhaps a robust common sense, sound judgment, and a hearty dislike of fads of all descriptions. Display and a desire for limelight had no place in his composition. He knew his job and he could do it, and he was content to let the results speak for themselves. Though he never went out of his way to court popularity he was much liked and respected by those with whom he worked. Dr. Manby was an enthusiastic golfer and lawn tennis player, and it was no easy matter to defeat him in either game, even during his last summer. He was a man of wide interests and at one time something of an authority on old furniture.

Dr. F. N. Kay Menzies writes: "Dr. Manby's sudden death is an irreparable loss to the poor-law medical service, especially of London. It is made doubly so by the fact that his old friend and colleague, Dr. Meredith Richards, was compelled to resign his position at the Ministry of Health in the spring of this year owing to serious illness. Manby and Meredith Richards knew more about poor-law medical work than any other medical men in existence, and the fact that they have both been lost to the service within the last few months is nothing less than a national misfortune. At a time like this their wide and matured experience, wise discretion, and sound judgment would have been of incalculable assistance to all those medical officers of health who will shortly be called upon to undertake responsibilities in connexion with the transfer of poor-law medical work to public health authorities. Manby's knowledge and experience of poor-law medical problems in the metropolis was profound and intimate and he was held in high esteem by the medical superintendents of the infirmaries, by whom his loss will be deeply regretted. His duties were often of a most difficult nature, requiring great patience and wisdom. He was always easily accessible, and could always be counted upon to give of his best in any direction which might be helpful to his colleagues."

Dr. Manby leaves a widow and one son.

JOHN MALLET PURSER, M.D., D.Sc. DUB., F.R.C.P. IREL.

Dr. John Mallet Purser died on Sept. 18th at his residence in Dublin, being within two months of completing his ninetieth year. He had suffered some severe illnesses within the past few years, but his extraordinary vitality brought him through, and although he was somewhat enfeebled in body his mental abilities had remained unimpaired.

Purser was educated at Trinity College, Dublin, and took his medical degrees in 1863. He subsequently took the Licences of the King and Queen's College of Physicians of Ireland and of the Royal College of Surgeons in Ireland, and in 1876 was elected a Fellow of the King and Queen's College of Physicians. From the beginning of his career he was a teacher. He held at once the posts of professor of anatomy and physiology in the Carmichael School of Medicine and lecturer in ophthalmology in Dr. Steevens' School. In 1870 he was appointed surgeon to the City of Dublin Hospital, a post which he soon exchanged for that of physician to the same institution. His career, however, took a definite line with his election in 1874 to the King's Professorship of the Institutes of Medicine in the School of Physic, Trinity College. He held this post, together with that of clinical physician to Sir Patrick Dun's Hospital, until 1901, when he decided to retire from active work. Nevertheless, in 1917, on the death of Dr. James Little, he consented to accept the chair of the Regius Professor of Medicine in Dublin University. In 1925 he retired from this last official connexion with Trinity College. His interest in the College did not cease, however, for shortly afterward he made it a gift of £10,000 to be employed for the advantage of the School of Physic and the other science schools of the College.

A bare recital of the offices held by Purser gives no conception of the part he played in the development of the modern school of medicine in Dublin. At the time of his appointment to the chair of the Institutes of Medicine the Dublin School was still under the dominance of the purely clinical ideas of Groves and Stokes. The influence of the latter, great as it had been and useful in its time, had now become a check on the introduction of ideas from any other source than the bedside. There were, it is true, grumblings against the dead hand of observational medicine which prevented advance. Purser made his position clear immediately on his accession to the chair by indicating that he intended to interpret "the Institutes of Medicine" as physiology and histology. Prior to this there was no regular instruction in physiology in the Dublin school, the previous professors having lectured in medicine. To his instruction in physiology and histology Purser added a voluntary class in pathology, which he conducted, unpaid, for more than 20 years, until the teaching of pathology was put on a regular basis in the school by the appointment of Dr. A. C. O'Sullivan as lecturer. He retired from private practice but performed the duties of clinical physician at Sir Patrick Dun's Hospital. It is difficult to say whether he shone most as lecturer in physiology or as clinical teacher. His ideas were clear and distinct, and his exposition of them lucid. He did not overburden his lectures with experiments, though employing them when they served to illustrate his subject. He had an unusual gift of logical thought, which made it easy for any intelligent student to follow his lectures and to carry away a sound knowledge of the essentials of physiology. His clinical teaching was, in effect, physiology (and pathology) illustrated in the living subject. He had the gift of conveying to his class the reasoning by which he passed from the signs and symptoms to the underlying functional and anatomical changes. Medicine was to him, and to his disciples, a science, incomplete, it is true, but always approaching completion. In treatment he was a sceptic. He had little belief in drugs as therapeutic agents. He was known to have said a good word for opium, and to have admitted that quinine had its uses, but for most drugs he cared nothing. The kind of reasoning on which pharmacology was built at that time excited his scorn. Of a book by Lauder Brunton he wrote a devastating review. No man distinguished more clearly between hypothesis and established fact. One consequence therefrom is that little if any of his positive teaching of 40 years ago is to-day unsound; it has been supplemented by the advance of knowledge, but rarely has it been falsified. This attitude toward medicine is a far step from that of the great Dublin clinicians, and Purser is rightly regarded as the leader in, and father of, modern medicine in Dublin. It was fortunate for Irish medicine that such a man was found at the moment when the new step was necessary. It is true that he wrote little. For this there were two reasons. His teaching duties kept him busy, and he read enormously that he might be fitted to teach progressively. But, more important than this, was the critical attitude which prevented him publishing anything to which he could not assign a high positive value. He published an admirable "Manual of Histology" in the early 'eighties, but he never troubled to issue a second edition.

Personally Purser was reserved, retiring, and modest. He disliked every kind of publicity. For example, he declined nomination for the Presidency of the Royal College of Physicians of Ireland when it was offered to him, on the ground that he was a physiologist, not a physician. His students were afraid of his sharp tongue—for no one could rebuke pretence or presumption more effectively—but they respected his conscientious performance of duty and his great ability as a teacher and man of science. As they knew him better the fear diminished and the respect increased. Those who came to intimacy with him realised the generosity of temper, the clear simplicity, and the wide range of culture. His leisure—scanty as it was during his tenure of the professorship—was given to reading, to travel, to art. In 1901, when Purser resigned the King's Professorship, his old pupils established a medal in the school in commemoration of his tenure of office, and the John Mallet Purser medal is awarded each year to the best student in physiology. Dr. Purser was unmarried.

Medical News.

UNIVERSITY OF LONDON: *University College.*—Forthcoming public lectures include a Rickman Godlee Memorial Lecture, by Viscount Grey of Fallodon, at 5.30 P.M. on Thursday, Nov. 7th; one on Medicine in the Days of Shakespeare, by Dr. Herbert Spencer, at 2 P.M. on Monday, Nov. 25th; and four on Secretion of the Digestive Juices, by Dr. R. J. Brocklehurst, at 5 P.M. on Mondays, Oct. 14th, 21st, and 28th, and Nov. 4th.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—Demonstrations of specimens will be given in the theatre of the College at 5 P.M. on Fridays, Oct. 18th and 25th, and Nov. 1st, by Sir Arthur Keith, F.R.S.; and at the same hour on Mondays, Oct. 21st and 28th, and Nov. 4th, by Mr. C. P. G. Wakeley. They will be open to advanced students and to practitioners.

BRITISH INSTITUTE OF PHILOSOPHICAL STUDIES.—Courses of lectures have been arranged by the Institute from Oct. 10th onwards, and particulars may be had from the Director of Studies (Mr. Sydney Hooper), 88, Kingsway, London, W.C. 2. Forthcoming courses include six lectures on Mind and Nature, by Prof. L. J. Russell; six on the Interpretation of Development and Heredity, by Mr. E. S. Russell, D.Sc.; and a series entitled an Introduction to Philosophy, by the Director of Studies.

ST. MARY'S HOSPITAL POST-GRADUATE COURSE will be held as usual during the first week-end of the autumn session. The 12 lectures, which are open to all medical practitioners without fee, will be held in the library of the Medical School (except the lantern lectures, which will be held in the Physiology Theatre) on Oct. 4th, 5th, and 6th. Particulars will be found in our Medical Diary.

HOSPITAL DINNERS.—The annual dinner of *King's College Hospital* will be held at the Connaught Rooms, Great Queen-street, London, W.C., on Wednesday, Oct. 2nd, at 7 for 7.30 P.M., with Dr. H. Willoughby Lyle, Dean of the Medical School, in the chair. As we have already announced, the centenary session will be opened at the Medical School, Denmark Hill, at 2.30 P.M. on the same day.—The *Westminster Hospital* dinner will be held at Grosvenor House, Park-lane, W., on Tuesday, Oct. 1st, at 7 for 7.30 P.M., with Mr. Stanley Dodd in the chair.

LONDON HOSPITAL MEDICAL COLLEGE.—The Schorstein Memorial Lecture will be delivered by Dr. A. F. Hurst on Friday, Nov. 8th, at 4.30 P.M., in the Bearstead Clinical Theatre. Dr. Hurst has chosen as his subject Precursors of Carcinoma of the Stomach, and all members of the medical profession are invited to attend.

ROYAL DENTAL HOSPITAL SCHOOL OF DENTAL SURGERY.—A conversazione and prize distribution will be held at this school, in Leicester-square, London, W.C., on Wednesday, Oct. 2nd, at 8 P.M., when Dr. William Hunter will preside and give an address to the students.

ROYAL INSTITUTE OF PUBLIC HEALTH.—The Council have completed the purchase of a freehold island site on the north side of Queen-square, Holborn, London, W.C., where it is proposed that the new premises of the Institute shall be erected.

COURSES IN GENITO-URINARY DISEASES.—At St. Paul's Hospital, Endell-street, Shaftesbury-avenue, London, W.C., a series of lectures on genito-urinary diseases will be given at 4.30 P.M. on Wednesdays from Oct. 2nd to Nov. 27th. Practitioners or students wishing to attend these lectures or the practice of the hospital may get further information from the secretary.

UNIVERSITY OF BIRMINGHAM.—Sir Farquhar Buzzard will deliver an address to students, entitled Arrogance and Ignorance in Medicine, on the occasion of the annual distribution of prizes on Tuesday, Oct. 1st. The ceremony will take place at 4.30 P.M. in the medical theatre of the University, Edmund-street.

UNIVERSITY OF DURHAM, COLLEGE OF MEDICINE.—The Duke of Northumberland, Chancellor of the University, will address the students in the College of Medicine, Newcastle-upon-Tyne, on Oct. 11th, at 4.15 P.M., on Some Scientific Theories and their Foundations at the opening of the winter session. A dinner will be held the same evening at the Central Station Hotel, Newcastle-upon-Tyne, at 7.15 for 7.30 P.M., when the Chancellor will be officially welcomed by the governors, Council, and staff of the College, and the University of Durham Medical Graduates' Association.

SURGICAL INSTRUMENT MANUFACTURERS ASSOCIATION.—The annual dinner of this Association will take place at the Holborn Restaurant on Friday, Oct. 11th, at 6.30 for 7 P.M.

FOOT HOSPITAL FOR MANCHESTER.—A new foot hospital was opened on Sept. 21st by the Dean of Manchester. The hospital is in Upper Brook-street, and has been established by the Incorporated Society of Chiropodists. It will be open in the evenings to suit working people, and will be carried on entirely by voluntary workers.

POST-GRADUATE COURSE AT THE LONDON HOSPITAL. It has been suggested that a post-graduate course for old students of the London Hospital should be held during the week of the annual dinner, which is arranged for Thursday, Oct. 17th, at the May Fair Hotel. Such a course will be held if there is enough demand, and the probable dates are Oct. 16th, 18th, and 19th.

QUEEN ALEXANDRA HOSPITAL, COSHAM.—The Committee appointed by the Minister of Pensions to inquire into the administration of this hospital is willing to consider relevant statements by patients, ex-patients, and others. They should be addressed to the Secretary of the Committee, Mr. R. Herbert, at 18, Great Smith-street, London, S.W. 1.

MANCHESTER WELFARE CENTRES.—The Manchester Corporation Public Health Committee have asked the city council for authority to assume control of three child welfare centres at Withington, Chorlton-cum-Hardy, and Didsbury —the only welfare centres in the city which still remain under the control of the School for Mothers.

DUDLEY MATERNITY HOME.—Last week the Countess of Harrowby opened a new maternity home and a nurses' home erected at a cost of over £30,000 by the Dudley Board of Guardians. The maternity home is a one-storey building intended to form an integral part of the large hospital which it is hoped to erect on the site. There are 11 beds in three wards, and a single-bed separation ward. The nurses' home provides housing for 02 nurses and probationers.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Sept. 30th, to SATURDAY, Oct. 5th.—BETHLEM ROYAL HOSPITAL, S.E. Tues. and Sat., 11 A.M., lecture demonstrations in Psychological Medicine.—PRINCE OF WALES'S GENERAL HOSPITAL, Tottenham, N. Special Course in Gastro-enterology. One week only. Further particulars from the Fellowship of Medicine.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, Sept. 30th.—2.30 to 5 P.M.: Medical, Surgical and Gynæcological Clinics. Operations.

TUESDAY, Oct. 1st.—2.30 to 5 P.M.: Medical, Surgical, Ear, Nose and Throat Clinics. Operations.

WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin, and Eye Clinics. Operations.

THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, Nose, Throat and Ear Clinics. Operations.

FRIDAY.—10.30 A.M.: Throat, Nose and Ear Clinics. 2.30 to 5 P.M.: Surgical, Medical, and Children's Diseases Clinics. Operations.

ST. MARY'S HOSPITAL POST-GRADUATE COURSE.

FRIDAY, Oct. 4th.—11–11.45 A.M., Prof. F. S. Langmead: Graves's Disease. 12–12.45 P.M., Dr. T. C. Hunt: Recent Aids in Diagnosis of Some Common Diseases. 2.15–3 P.M., Mr. Aleck W. Bourne: The Action of Certain Drugs on the Uterus in Labour (Lantern Lecture). 3.15–4 P.M., Dr. A. Hope Gosse: Lantern Demonstration concerning Diseases of the Chest.

SATURDAY.—10.15–11 A.M., Mr. Duncan C. L. Fitzwilliams: Treatment of Malignant Disease by Radium. (With Epidiascope.) 11–11.45 A.M., Sir William Willcox: Catarrhal Jaundice. 12–12.45 P.M., Dr. Robt. Hutchison: Common Dyspepsias of Childhood. 2.15–3 P.M., Mr. T. G. Stevens: Retention of Urine in Women. 3.15–4.15 P.M., Dr. Albert Eidinow: Clinical Methods in Light Treatment.

SUNDAY.—10.15–11 A.M., Mr. R. M. Handfield-Jones: Pitfalls in Urological Diagnosis. 11–11.45 A.M., Dr. C. M. Wilson: Diabetes. 12–12.45 P.M., Mr. V. Zachary Cope: Abdominal Pain.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

THURSDAY, Oct. 3rd.—5 P.M.: Dr. J. H. Stowers: Introductory Lecture.

CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL, Gray's Inn-road, W.C.

MONDAY, Sept. 30th.—1.30 P.M.: Hearing Tests.

WEDNESDAY, Oct. 2nd.—1.30 P.M.: Examination and Diagnosis: The Sinuses.

ST. PAUL'S HOSPITAL, Endell-street, W.C.

WEDNESDAY, Oct. 2nd.—4.30 P.M., Mr. H. P. Winsbury White: Stone in the Upper Urinary Tract.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE.

TUESDAY, Oct. 1st.—4.15 P.M., Mr. F. G. Wrigley: Acute Suppurative Otitis Media.

FRIDAY.—4.15 P.M., Dr. R. Prosser White: Some Problems in Occupational Dermatitis.

Appointments.

REDMOND, W. A., M.B., Ch.B. Dub., has been appointed Medical Officer, Ballyward Dispensary District, Co. Down.

SIMS, CARRIE, M.B., Ch.B. Birm., D.P.H., Medical Officer on the Staff of the Ministry of Health.

SPICKET, J. S., L.R.C.P. Lond., M.R.C.S., District Medical Officer, Haverfordwest Union.

THOMAS, D. M., L.R.C.P. Lond., M.R.C.S., Public Vaccinator for Greenwich District.

WILSON, H. F., Certifying Surgeon under the Factory and Workshop Acts for the Carnoustie District of the County of Angus.

Queen Charlotte's Maternity Hospital: DOLEMAN, F. T., L.R.C.P. Lond., M.R.C.S., Senior Resident Medical Officer; HUGHES, T. L., L.R.C.P. Lond., M.R.C.S., Assistant Resident Medical Officer; KINGSMILL, C. M., M.B., B.S. Lond., District Resident Medical Officer; and LIEBEN, C., L.R.C.P. Lond., M.R.C.S., Resident Anæsthetist.

Vacancies.

For further information refer to the advertisement columns.

Aberdeen Royal Mental Hospital.—Jun. Asst. P. £250.

Aberystwyth Infirmary and Cardiganshire General Hospital.—H.S. £200.

Albert Dock Hospital, Connaught-road E.—Surgeon.

Bath, Somerset and Wilts Central Children's Orthopædic Hospital, Coombe Park.—H.S. At rate of £120.

Belgrave Hospital for Children, 1, Clapham-road, S.W.—H.S. Also Asst. H.P. Each at rate of £100.

Birkenhead General Hospital.—Cas. S. £100.

Birmingham, Dudley Road Hospital.—Jun. Asst. M.O. At rate £200.

Birmingham, Selly Oak Hospital.—Res. Physician. £100–£600.

Birmingham City Education Committee.—Asst. School M.O. £600.

Blackburn and East Lancashire Royal Infirmary.—Fourth H.S. £130.

Bootle Borough Hospital, Derby-road.—Hon. Asst. Gynæcological Surgeon.

Brighton, Royal Sussex County Hospital.—H.P. £150.

Bristol Dispensary.—Non-Resident M.O.

Cambridge, Addenbrooke's Hospital.—Hon. Asst. P.

Cambridge, Papworth Village Settlement.—Second Asst. M.O. £300. Also H.P. At rate of £100–£200.

Cardiff, Glan Ely Tuberculosis Hospital, Fairwater.—Asst. Res. M.O. £250.

Carmarthen Joint Counties Mental Hospital.—Jun. Asst. M.O. £300.

Central London Throat, Nose and Ear Hospital, Gray's Inn-road, W.C.—Hon. Chief Clin. Assts.

City of London Hospital for Diseases of the Heart and Lungs, Victoria Park, E.—H.P. At rate of £100.

Eastern Dispensary, Leman-street, E.—Physician.

Exeter, Royal Devon and Exeter Hospital.—Hon. Physician.

Gloucester, Gloucestershire Royal Infirmary, &c.—Hon. S. to Ear, Nose and Throat Dept. Also First H.S. At rate of £135.

Great Yarmouth General Hospital.—Sen. H.S. £150. Also Jun. H.S. £100.

Grosvenor Hospital for Women, Vincent-square, S.W.—Res. M.O. At rate of £100.

Highgate Hospital, Dartmouth Park Hill, N.—Third Asst. M.O. £350.

Hospital for Consumption and Diseases of the Chest, Brompton, S.W.—H.P. At rate of £50.

Hospital for Epilepsy and Paralysis, Maida Vale, W.—Res. M.O. Also H.P. At rate of £150 and £100 respectively.

Hospital of St. John and St. Elizabeth, Grove End-road, N.W.—Res. H.S. At rate of £75.

Hull Royal Infirmary.—Asst. H.P. At rate of £130.

Isleworth, West Middlesex Hospital.—Res. Asst. Med. Supt. and Asst. M.O. £150.

Kingston and District Hospital.—Third Asst. Res. M.O. At rate of £250.

Larbert, Stirling District Mental Hospital.—Third Asst. M.O. £250.

Leeds Public Dispensary.—Jun. Res. M.O. £150.

Liverpool Hahnemann Hospital, Hope-street.—Stipendary M.O. At rate of £125.

Liphook, Hants, King George's Sanatorium for Sailors.—Asst. M.O. At rate of £200.

London Homœopathic Hospital, Great Ormond-street, W.C.—Surgeon in charge of the Mechanotherapy and Orthopædic Dept.

London Jewish Hospital, Stepney Green, E.—Hon. Asst. Radiologist. Also Hon. M.O. in charge of Actino-Therapeutic Dept.

London Temperance Hospital, Hampstead-road, N.W.—Res. M.O. At rate of £175.

Manchester Ear Hospital, Grosvenor-square, All Saints.—H.S. At rate of £150.

Newcastle-upon-Tyne Eye Hospital.—H.S. £200.

Nottingham City Mental Hospital.—Jun. Asst. M.O. £350 to £400.

Paddington Green Children's Hospital, W.—H.P. and H.S. Each at rate of £150. Also Anæsthetist, £75.

Prince of Wales's General Hospital, Tottenham, N.—Sen. H.P. Sen. H.S., and Special H.S. Each at rate of £120. Also Jun. H.P., and Two Jun. H.S.'s. Each at rate of £90.

Princess Louise Kensington Hospital for Children, North Kensington.—H.P. At rate of £75.

Rotherham Hospital.—H.P. £180.

Royal Free Hospital, Gray's Inn-road, W.C.—Sen. Res. M.O. *£150. Also Cas. O. £150.*

Royal National Orthopædic Hospital, 234, Great Portland-street, W.—Hon. Asst. Surg. Also Surg. Registrars. Each £105.

Royal Naval Medical Service.—Vacancies for Medical Officers. £452–£2350.

Saint Mark's Hospital for Cancer, &c., City-road, E.C.—H.S. At rate of £75.

Sheffield, South Yorkshire Mental Hospital.—M.O. £400.

St. Peter's Hospital for Stone, Henrietta-street, W.C.—Radiologist. £25.

St. Stephen's Hospital, 369, Fulham-road, S.W.—Third Asst. M.O. £300.

Southampton Free Eye Hospital.—H.S. £150.

Stafford, County Mental Hospital.—Second Asst. M.O. £600.

Sudan Medical Service.—M.O. £E720.

Swansea Hospital.—H.S. £150.

West London Hospital, Hammersmith, W.—Hon. Registrar for Throat, Nose, and Ear Dept. House Officer for Children's Dept. At rate of £150. Asst. M.O. At rate of £450. Also three Jun. Asst. M.O's. Each at rate of £350.

Weston-super-Mare, General Hospital.—Res. H.S. £130.

Willesden General Hospital, N.W.—Ophthalmic S. Res. H.S. At rate of £100. Also Physician.

Winchester, Royal Hampshire County Hospital.—Res. H.S. At rate of £150.

Wolverhampton Royal Hospital.—Res. M.O. At rate of £150.

Woolwich and District War Memorial Hospital, Shooter's Hill, S.E. Res. M.O. £175. Also H.S. At rate of £125.

The Chief Inspector of Factories announces vacant appointments for Certifying Factory Surgeons at Ludlow (Salop), and Topsham (Devon).

The Secretary of State for the Home Department gives notice of a vacancy for a Medical Referee under the Workmen's Compensation Act for the Districts of the Bath, Calne, Chippenham, Devizes, Frome, Hungerford, Malmesbury, Marlborough, Melksham, Newbury, Swindon, Trowbridge and Warminster County Courts (Circuit No. 52). Applications should reach the Private Secretary, Home Office, Whitehall, London, S.W., not later than Oct. 14th.

Births, Marriages, and Deaths.

BIRTHS.

Chapman.—On Sept. 20th, at Marine House, Bridlington, Yorks, the wife of P. D. H. Chapman, M.B., B.Ch., of a daughter.

Fitzsimons.—On Sept. 19th, at Albany-road, Cardiff, the wife of Dr. R. A. Fitzsimons, of a daughter.

Frazer.—On Sept. 22nd, at Mowbray-road, Brondesbury, N.W., to Dr. Kathleen Frazer, the wife of R. B. F. Frazer, L.R.C.P., Barrister-at-Law—a daughter.

Muir.—On Sept. 22nd, at Sussex House, Sutherland-avenue, W., the wife of J. B. G. Muir, M.B., B.S., F.R.C.S., of a son.

MARRIAGES.

Johnston—Rooke.—On Sept. 19th, at the Presbyterian Church, Camp Hill, Birmingham, William Macdonald Johnston, M.B., Ch.B., Crouch Hill, N., to Nancy Rooke, of Egbaston, Warwickshire.

Mitchell—McConnell.—On Sept. 4th, John Myles Mitchell M.B., B.Ch., B.A.O., to Adelaide Patricia, youngest daughter of T. E. McConnell, C.B.E., and Mrs. McConnell, of Belfast.

DEATHS.

Allan.—Thomas Sprot Allan, L.R.C.P., L.R.C.S. Edin., L.F.P.S. Glasg., Lieut.-Colonel R.A.M.C. (T.F.) (retired) late Surgeon R.M.S. *Appam*, Elder Dempster and Co., Ltd. Age 65, at the "Robert Davies" Nursing Home, Liverpool, on Sept. 16th after an operation. Interred at Allerton Cemetery, Liverpool, on the 19th inst.

Bowhay.—On Sept. 17th, at Yelverton, Devon, Albert Bowhay, M.D., late of Gunnislake, Cornwall, aged 67.

Coope.—On Sept. 24th, of acute poliomyelitis, Jean Rosemary, aged 5½ years, daughter of Dr. and Mrs. Robert Coope, of 13, Rodney-street, Liverpool.

Manby.—On Sept. 20th, at Palace Gardens-terrace, W., Edward Petronell Manby, M.D., Med. Off., Min. of Health.

Williams.—On Sept. 17th, at Richmond, Yorkshire, Howell Williams, M.D., aged 84.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of [illegible] *rriages, and Deaths.*

Births, Ma

Notes, Comments, and Abstracts.

"THE WEEKLY WEATHER REPORT."

From 1878 until February of last year a report on weather conditions was issued week by week by the Meteorological Committee. The place of these has now been taken by an annual volume which retains the original title. The first of these, now before us,[1] refers to the figures for the year 1928/29. The main feature of the report is a collection of statistics on the temperature, rainfall, and sunshine for a number of districts of the British Isles, from which long period normals for the different periods and districts have been calculated for each week of the year. The table of normals for mean temperature, number of rain days, rainfall, and daily duration of sunshine for each of the 12 districts of the British Isles and for each of the 52 weeks of the year is in fact based on observations for the 35 years 1881/1915. For each district the deviation from the normal during the year is shown in respect of temperature, rainfall, and bright sunshine. Observations at Kew Observatory for the 20-year period 1907/26, compared with the 35-year period 1881–1915, indicate that the summers in southern England have become cooler and the winters warmer in recent years. The records of bright sunshine, that is to say, sunshine sufficiently intense to make a charred trace on the card of a Campbell-Stokes recorder with a 4-inch spherical lens, indicate that smoke pollution may make itself felt at a considerable distance from its source. The sunshine expressed as a percentage of the possible duration for the year was in York only 28, while in Southport it was 33; for the winter the figures were 12 and 18 respectively. And this difference might be anticipated owing to the prevalence of westerly and south-westerly winds which carry the smoke of the industrial area away from Southport and towards York. This is only one example of the use to which the wealth of accurate information contained in this report can be put.

IRONSTONE AND LIGHTNING.

At an inquest at Worth on Sept. 10th, on two people who had been killed by lightning on the previous afternoon, the theory was advanced that the lightning was attracted by an under-crop of ironstone rock which is to be found in a large area of North Sussex. Four men were working in a field picking potatoes when the storm broke, and they ran to an oak tree for shelter. The tree was not struck but two of the men, one aged 25, and the other 42, were killed; also two dogs. One of the other men said his legs felt numb for some time, and the shock was as though his knees had been hit by a sledge-hammer. The fourth, a boy, was not much affected. Dr. A. Grayling stated that the cause of death was shock from lightning. Evidence of the lightning having struck the men was to be seen by the curious arborescent marks upon their bodies. Dr. Grayling added that in some parts of Sussex there were quantities of under-crops of ironstone rock, and that would attract electrical discharge. It was possible that in some parts of the particular field there was such an under-crop. Dr. E. F. Hoare, the East Sussex coroner, returned a verdict of death from misadventure.

A CAUTIONARY NOTICE.

Members of the medical profession often receive begging letters from persons claiming to be either widows or daughters of doctors. When such letters are forwarded to the secretary of the Royal Medical Benevolent Fund for inquiry it may be found that the person is known in the office of the Fund as one not deserving of charity. In the interests of medical charity the secretary of the Fund asks that letters *from persons unknown asking* for assistance should be forwarded to him at 11, Chandos-street, London, W. 1, for inquiry and report.

---

[1] H.M. Stationery Office. 15s.

Asthma Research Council.—The Council's new address is 37, Russell-square, London, W.C. 1, and the telephone number Museum 3313.

New Casualty Department at Nottingham.—The great increase in the number of accidents has made it necessary to enlarge the casualty department of Nottingham General Hospital. There are now separate entrances for walking and stretcher cases, an anæsthetic room, surgeries for men and women, an operating theatre, and two recovery rooms.

An Address

ENTITLED

ARROGANCE AND IGNORANCE IN MEDICINE.

Delivered at the Birmingham University Medical School on Oct. 1st, 1929,

By Sir E. FARQUHAR BUZZARD, Bart.,
K.C.V.O., M.D. Oxon.,
CONSULTING PHYSICIAN TO ST. THOMAS'S HOSPITAL; REGIUS PROFESSOR OF MEDICINE IN THE UNIVERSITY OF OXFORD.

We cannot blind ourselves to the *fact* that the present position and reputation of the medical profession in the eyes of the public is unsatisfactory. We cannot remain deaf to the censure, sometimes good-natured, sometimes ill-natured, well-founded or baseless, so frequently passed in ordinary conversation on doctors and doctoring. It is not easy to treat as they deserve the cheap sneers which emanate so glibly from the judicial bench, nor to overlook the odious comparisons drawn between qualified and unqualified practice in the columns of our sensational and not too scrupulous newspapers. We are blamed, *almost in one* breath, for our conservatism, our radicalism, and our trades-unionism. There can be little doubt that, speaking generally, we live in an atmosphere which may be described as unsympathetic and suspicious, if not actually antagonistic. It may be that such an atmosphere is beneficial to our health, although I doubt it; at any rate we can do no harm and may do good if we investigate its properties and perhaps suggest such measures of ventilation as may appear to be desirable.

The charges laid against us are many, but they may be divided roughly into two groups, those of Arrogance and those of Ignorance. Let us examine the evidence which can be brought to support them, and if we are found guilty, as I have no doubt we shall be, let us hear what can be stated in mitigation. It might save the time of the Court if we plead guilty at once to both charges, and confine ourselves to pleas of justification or provocation.

ARROGANCE.

The indictment of Arrogance is laid in the following *terms*: "You are inclined to treat your patients as fools, to be too cocksure, and to lay down the law as if you were infallible; you won't listen to what we have got to say, and you are intolerant of the views of others."

The terms of such an indictment are general rather than specific, but certainly contain more than a grain of truth. The answer to them must also be general, and relies for its sufficiency on rather wide considerations which I must endeavour to formulate as briefly as possible.

It must be remembered, in the first place, *that at* the time of qualification a medical practitioner has spent at least seven years pursuing an educational curriculum which bears no resemblance to that through which the large majority of his patients have passed. In addition to mastering the principles of physics, chemistry, and biology, he has spent at least two years in the study of human physiology and anatomy, and at least three more years in acquiring some knowledge of pathology, medicine, surgery, midwifery, and a number of other special subjects. The load of information he has ingested is enormous, probably much greater than he has had time to digest, but that does not constitute the essential difference in his education from that of his future patients. During the whole of these seven years he has been trained in precise methods of investigation, has learnt to think scientifically, and to speak in scientific terms, to distinguish between facts and theories, to regard a priori conceptions with suspicion, to appreciate the value of experiments and controls, and generally has developed a critical faculty of which the lay mind is, perhaps mercifully, completely innocent.

Removed from his hospital, separated from his fellow students and teachers, and flung into practice, he finds himself in another world, where he is called upon to discuss medical matters with patients who, nominally educated, are not only ignorant of the rudiments of science, but who are often incapable of clear thinking *or clear expression. He finds that their answers* are unrelated to his questions, their beliefs are confused with facts, that the identity of post hoc with propter hoc is accepted without reserve, and that hearsay evidence is treated with the greatest respect. In short, he quickly realises that discussions on questions of health and ill-health are about the most difficult and exacting of the tasks with which he is confronted. If he is wise, and if he values the status of his profession, he will set himself to study this aspect of his work with the devotion he gave to his study of pathology. He will train himself to answer questions with the truth and nothing but the truth, even if he does not always feel justified in imparting the whole truth. He will learn to use language intelligible to his interrogators and he will never hesitate to express his doubts or his ignorance where his patient's welfare is at stake. Lastly, he will be prepared to give unlimited time and attention to practising the arts of listening and questioning, perhaps the most important part of his professional equipment.

Questions and their Answers.

If he is unwise and impatient he will evade inquisition, ask few questions, turn a deaf ear to stories which may be gold mines of information, and eventually justify the accusation of arrogance. It is not difficult to find excuses for this line if he has chosen it. It may be urged on his behalf that he has not the necessary time to give to the task, or that his attempts to accomplish it have always failed, his explanations having been misinterpreted and his opinions wrongly reported. Little wonder, perhaps, that he has taken the path of least resistance, although at the same time he has closed the door on the possibility of establishing that mutual confidence between doctor and patient which is essential to successful practice.

Although Medicine, year by year, is becoming more scientific in methods of investigation, no medical man can afford, and the profession cannot afford, to neglect the art of questioning or the art of listening. Therein lies an economic problem, the solution of which must some day be sought and found, but which would occupy more time than I can spare for its elaboration now. I refer to the fact that in general practice it is often impossible for a doctor to give to each patient the time necessary, not for physical examination, but for verbal cross-examination, and yet see a sufficient number of patients to earn a living wage. Skilful cross-examination will often define, and thus limit the field of, the necessary physical and chemical examination, but it requires time and perseverance, because what the doctor wants to learn, and *what the patient* thinks the doctor wants to learn, are rarely the same thing. The doctor may readily earn a reputation for arrogance if he cannot conduct his cross-examination with tact as well as with intelligence.

IGNORANCE.

And now for ignorance; our ignorance and that of the public. Ours is comparative, the public's is superlative. Our knowledge of the factors underlying health and disease, although comparatively small, is infinitely greater than it was even 50 years ago, and is steadily increasing. *This knowledge is the standard* by which we judge ourselves, but, in the public eye, our knowledge is measured entirely, and perhaps naturally, by our ability to cure. We are criticised, for instance, because we can cure neither cancer nor the common cold, and our critics assume that our ignorance of both conditions is something of which we may well be ashamed. Perhaps, but we can put up some kind of defence. In the first place, the criticism is based on an assumption, a relic of mediæval belief, that there are so many diseases for every one of which a cure exists, if we are clever enough to find it. Such an assumption cannot really be supported for a moment by any reasonable argument, and, in fact, the more we know of disease the more does it appear to lack foundation. The claims for prevention of disease, on the other hand, are becoming daily more firmly established, and the future of medicine surely lies in that direction.

The Public Demand for Cures.

A cure for cancer is loudly demanded by the public, and every effort has been and is being made to meet that demand by attempts to discover the cause or origin of that disease. In this case we are not justified in assuming that it can be cured or prevented, even if all its mysteries are revealed.

The common cold is on a different footing, and we may probably claim to know all the material facts about it. It is not curable, because it is only the manifestation of a battle royal between invading microbes and the tissues of their victim, and all we can do is to render aid to the latter in order to shorten the struggle and hasten his almost inevitable victory. It is probably preventable, but effectual preventive measures would produce such a social upheaval, and raise such an outcry from the public, that no Minister of Health is ever likely to risk his position or his parts by bringing them into force.

Diseases may probably be divided into several groups: (1) the curable, (2) the preventable, and (3) a group comprising those about which we know too little to determine the scope of their preventability. Of these three groups the smallest is the curable, and it is safe to predict that it will always remain so, while we may legitimately hope that the preventable group will gradually increase.

Let me add, in confidence, that there is yet another group of diseases, by no means insignificant in size, which are never cured, but which almost invariably disappear without, and sometimes in spite of, medical treatment. I might go further and point out that there are many diseases afflicting mankind to which the idea of cure is not, nor is ever likely to be, applicable. Take, for instance, "infantile paralysis" or acute poliomyelitis. Seeing its lamentable results, the public naturally assumes that we know nothing about it. If we did, we ought and should be able to cure it. But that is not the case. We know a great deal about it, and the more we know the less likely does it appear that a cure will ever be forthcoming. That it is preventable, that under certain circumstances it may be possible to arrest it, are well-founded beliefs, which we are justified in holding, but a cure for the disease can only be hoped for by those who really *are* ignorant of its pathology.

Response to the Demand.

We need not lie awake and fret about this aspect of our ignorance, provided we do not as a profession claim to cure disease. That is a claim we may well leave to quacks and charlatans, who will always find a public ready to believe them. On the contrary, it should be our object to make our methods of practice and our claims so different from those of quacks that the public should have no difficulty in distinguishing them. Therein we fail, and thereby we must plead guilty to a charge of ignorance. How can we expect to be acquitted of such a charge when we see the profession taking up, and following like a flock of sheep, each new "cure-all" stunt as it is offered to it? Sour milk, hormones, all forms of electricity, and lastly, ultra-violet rays, to mention only a few, have all been exploited by the profession with so little discrimination that a public cannot but fail to distinguish between qualified and unqualified practice. Without diagnosis and without dignity have doctors applied such measures, each in its turn, to every known ailment, with the result that our wisdom and our honesty, as well as the merits of the curative agent itself, have often become discredited. And our only defence is based on the statement that patients insist on having the newest thing in the way of cures! A very poor excuse, and one quite unworthy of the profession whose scientific status we are anxious to raise.

Perhaps my indictment is drawn in somewhat strong terms, but I should not be exaggerating very greatly if I said that I never see a patient nowadays who has not already been lavishly exposed to artificial or natural sunlight—not a very good advertisement for Old King Sol, or his synthetic offspring!

Psychological Training.

Yet another aspect of our ignorance on which stress is often, and not always undeservedly laid. It is, perhaps, again the fault of an overcrowded curriculum that the psychological side of our work does not receive the attention which is its due. Every patient is an individual with his own idiosyncrasies and with his own reactions. We are accused of treating them as if they were all alike, and of ignoring their personal characteristics or peculiarities. The art of recognising such features is not an easy one to acquire, but time and labour spent in that direction is not wasted, even if the results obtained may sometimes upset the lessons we have learnt from clinical signs or from boiling test-tubes. A doctor is apt to be classed as ignorant, perhaps even arrogant, if he has not earned the title of "understanding."

THE TRUE RÔLE OF MEDICAL MEN.

I cannot here exhaust the whole sum of our iniquities, but I hope to have indicated some of the lines along which future generations of doctors may count to correct the mistakes of their misguided predecessors. In order to dissipate any gloom I may have produced, I would like to add a few words of reassurance and encouragement. The criticisms, just and unjust, to which I have referred are levelled at professional practice as a whole, rather than at doctors individually, each of whom has it in his power to earn the respect, gratitude, and affection of his patients. The personal status of the doctor depends, not so much on his knowledge or ignorance, his modesty or arrogance, as on his willingness or unwillingness to place all, or more than all, his resources at the disposal of those who seek his help. If I were permitted to coin a motto, appropriate alike to consulting-room and surgery, it would be "Give and do more than is required of you."

Let me close with a short but true story. A few weeks ago I was staying at an hotel in the south of England, and one evening I received a message to the effect that Lord Mersey, an old and eminent judge, who has since passed away, would like to have a few words with me. He greeted me in the following way: "I wanted to make your acquaintance because I knew and greatly respected your father. Many years ago, towards the end of a long illness, he was asked to see me. After consultation with the other doctors, he came back to my bedside and said, 'I don't know what is the matter with you, but I am confident that you will make a complete recovery.' He was quite right, and I have never forgotten the comfort and hope with which his words inspired me."

To the unthinking my father's words might have sounded like a confession of ignorance. To a great lawyer they appeared to be based on knowledge. There was no claim, no promise, to cure; only confident prophecy, born of experience. If our profession as a whole is to attain its rightful position let it cease to profess to cure, and be content to show the public that its knowledge and experience, limited as they yet must be, are assets of value on which reliance can be safely placed.

YORKSHIRE VOLUNTARY HOSPITALS FUND.—The East and West Ridings Voluntary Hospitals Committee has now been enlarged by the inclusion of the North Riding, which has hitherto had a separate committee. The purpose is to accomplish for Yorkshire what King Edward's Fund does for London, and the new fund will be known by the name of Princess Mary, who is the patron; Lord Lascelles will be the President. During the financial year just ended the old committee raised nearly £8000.

ON THE ALLEGED

EXPERIMENTAL PRODUCTION OF MALIGNANT TUMOURS IN THE FOWL.

By A. M. BEGG, M.B., CH.B. N.Z.,
AND
W. CRAMER, PH.D. BERLIN, D.Sc. EDIN.,
M.R.C.S. ENG.

(From the Laboratories of the Imperial Cancer Research Fund.)

IN recent years statements have appeared repeatedly in the cancer literature to the effect that it is possible to transform normal fowl cells rapidly by a simple experimental procedure into malignant cells. The first statement of this kind was made by Carrel, who claimed to have obtained a malignant tumour of the fowl by injecting a normal fowl with normal embryo emulsion and certain chemicals, such as arsenious acid, indol, skatol, and tar. One of these tumours is still being propagated in various laboratories and appears in the literature as "Carrel's indol tumour." Later Carrel's procedure was modified by his pupil A. Fischer and his collaborators, who cultivated normal fowl cells in vitro together with various chemical substances such as arsenious acid, and claimed to have produced a transformation in vitro of normal cells into malignant cells, so that the tissue cultures, when injected into normal fowls, produced a malignant new growth. In one of these experiments, published from Fischer's laboratory by Laser, the transformation was effected by cultivating normal cells of the fowl in the serum of another fowl which had received injections of tar. Even simpler was the procedure of Haagen, who cultured normal monocytes of the fowl in the ordinary way in vitro, and on injecting these cultures, together with dilute arsenious acid into six fowls, obtained, after three weeks in four of these animals, large, rapidly metastasing tumours, which, according to the description, were typical Rous tumours No. 1.

The experiments of Carrel, which are technically the simplest to perform, have been repeated in many different laboratories by experienced workers (Deelman, Roussy, Pentimalli) with uniformly negative results. Although the failure to confirm these results has been published, Carrel has not communicated any further experiments confirming his positive results.

At the International Congress of Cancer in 1928 A. Leitch and J. B. Murphy reported that they had been able to produce a malignant new growth in fowls by the injection of materials derived from normal fowls. Leitch obtained this result with the extract of a normal fowl's pancreas, while Murphy claimed to have succeeded with material obtained from a normal fowl's testicle. In the Annual Report of the British Empire Cancer Campaign for 1929 Leitch reported that, in spite of numerous repetitions of these experiments, he had been unable to confirm either his own result or those of Murphy. Murphy himself has not published a confirmation of his preliminary communication.

One curious feature of these observations is that the malignant tumour produced in all these experiments is always of the same type—namely, a sarcoma closely resembling in its histological appearance and its biological characters, such as filtrability, rate of growth, the Rous tumour No. 1. This is the filtrable tumour of the fowl which is being propagated in all the laboratories from which claims as to the alleged transformation of normal cells of the fowl into malignant cells have been published. But the spontaneous appearance of this type of tumour is by no means a particularly frequent event. Rous himself described over 40 tumours of the fowl; of these only six were filtrable, and of these six tumours only one (No. 43) had the same histological appearance and biological character (rate of growth, &c.) as Rous tumour No. 1, while two other filtrable tumours (Nos. 18 and 33) resembled each other, but differed in their histological appearance quite definitely from the tumour No. 1. Fujinami has described 32 carcinomata and seven sarcomata occurring in fowls, and of these only one resembled in its histological appearance and its biological characters the Rous tumour No. 1. Pentimalli has described 18 spontaneous tumours of the fowl, of which one was a carcinoma. None of the 17 sarcomata resembled the Rous tumour No. 1. In our laboratory, in which a large number of fowls of all ages have been under observation during the last five years, five spontaneous tumours have been found. Of these, two developed the property of filtrability, but both differed widely from each other and from the Rous tumour No. 1 in their histological appearance and their rate of growth. In this connexion we may also refer to a hitherto unpublished result obtained by our late colleague, Dr. B. R. G. Russell. By repeated subcutaneous injections of tar into fowls he succeeded in producing a hard tumour in one fowl after more than a year. Histologically it was a fibrosarcoma; transplantation with living cells gave negative results, and it showed no resemblance to the Rous tumour No. 1.

It is clear, therefore, that so far as the spontaneous development of malignancy in fowls is concerned, the same degree of variability exists as in mammals, and that the Rous tumour No. 1 does not represent a particularly frequent type of malignancy in fowls. The fact that the *alleged* experimental transformation of normal cells of the fowl into malignant ones always leads to the same type of tumour is, therefore, a feature which requires explanation, especially when one takes into consideration that the experimental conditions under which this same type of tumour was *apparently* produced from normal cells differed widely both as regards the normal cells and the material which was allowed to act upon them.

A Source of Fallacy.

During the last three years repeated attempts have been made in this laboratory to test the validity of the contention put forward by Carrel and his pupils. Quite recently experiments have been carried out to test also the results obtained by Leitch with material obtained from the pancreas of normal fowls. All of them have yielded negative results. But one of these experiments has accidentally disclosed an experimental fallacy adequate to account for the positive results which have been recorded. In view of the importance which attaches to experiments of this kind in regard to our conceptions of the ætiology of cancer, this experiment will be described in detail.

It is well known that malignant tumours of the mouse, or extracts prepared from them, do not cause malignant disease when injected into fowls. Our own experiments have also convinced us that pancreas or pancreatic extracts of a normal fowl when injected into a fowl do not produce a tumour, and the recent report of Leitch referred to above is in agreement with this. An experiment was therefore planned in which extracts from a mouse tumour were inoculated repeatedly into a normal fowl, which was subsequently to receive an extract from the pancreas of a normal fowl.

In this experiment five chicks of Exp. A had received injections once a week for three weeks of an extract from mouse carcinoma 63. The extract was made by rubbing the carcinoma in a mortar with sand and Ringer's solution, and after spinning the turbid extract filtering it through a Berkefeld filter. The last injection of the mouse tumour extract had been given on May 30th. On the same day a new experiment was started, and the same extract of carcinoma 63 as that given to the five chicks of Exp. A was injected into two new chicks (Exp. B). Four days afterwards the five chicks of Exp. A received an injection of a pancreatic extract from a normal fowl; the two chicks of Exp. B did not receive this pancreatic extract.

A fortnight after the last injection of the carcinoma extract all the five chicks of Exp. A and the two chicks of Exp. B had developed tumours at the site of inoculation of the mouse carcinoma extract. The tumours grew very rapidly, histologically they were identical with the Rous tumour No. 1; they could be transmitted by extracts to other fowls. In fact, the result was exactly as if these seven chicks had received an injection of an active filtrate of Rous tumour No. 1.

It is clear that the positive result, which resembled those obtained by Carrel, Leitch, Murphy and others, had nothing to do with the injection of the pancreatic extract, because the tumours formed equally well in the two chicks of Exp. B which had received the injection of the mouse carcinoma extract only. The formation of these tumours was therefore clearly associated with the injection of the mouse carcinoma extract on a particular date—namely, May 30th. As soon as this was realised the experimental conditions obtaining on that day were reconstructed from the protocols, with the following result. The experiment just reported had been carried out in the afternoon. In the morning another experiment had been carried out in which an extract had been made from three different Rous tumours and inoculated into fowls. The routine of this laboratory is that the mortars used for preparing these extracts after washing and drying are sterilised. Three sterile mortars are available and all the three mortars had been used in the forenoon. They had then been washed in running water and dried, but there was no time to sterilise them for the experiment in the afternoon. The mortar used in the afternoon for the extraction of the mouse carcinoma had therefore been used in the morning for the extraction of a Rous sarcoma. Sterility of the mortar from *bacterial* contamination was not essential in preparing the extract, as it was passed through a Berkefeld filter before injection. The possibility that the mortar was still contaminated with the Rous "agent" in spite of the washing was not taken into consideration, but the result shows that in spite of the washing it still contained active material from a Rous sarcoma, which must have exhibited virulence of a high order. The virulence of the Rous sarcoma extracts show very wide fluctuations, as was shown by Gye and Andrewes, and has since been confirmed. Baker and McIntosh, for instance, state that filtrates of the tumour give sometimes positive results after the injection of as little as 0·001 c.cm. of the extract contained in 0·5 c.cm. saline, while at other times 1 c.cm. of the extract has failed to produce a tumour.

This experiment emphasises the necessity for all laboratories in which the Rous tumour No. 1 is being propagated of subjecting all apparatus used in experiments on fowls to a process of sterilisation which will ensure the destruction of the "agent." Unless this precaution is observed the inoculation of material which in itself is inactive may by contamination produce a typical Rous tumour No. 1. The experiment here described has been repeated five times, observing the precaution just mentioned. The results were uniformly negative.

Conclusion.

The alleged experimental transformation of normal cells of the fowl into malignant cells by simple chemical substances is based on isolated experiments, in which the tumours produced always had the histological appearances and biological features of Rous tumour No. 1. In view of this peculiar feature and the failure to confirm these results, they must be ascribed to an experimental error similar to that responsible for the positive results obtained in the experiment described in this paper.

THE ULTIMATE PROGNOSIS IN CASES OF ECLAMPSIA AND ALBUMINURIA OF PREGNANCY.*

By JESSIE C. B. SYM, M.D. EDIN.

ECLAMPSIA has long been recognised as one of the formidable risks of child-bearing. From the Registrar's reports for England, Wales, Scotland, and Ireland it appears that, on an average 600 women die annually of eclampsia in these islands. The fœtal mortality is extremely high and, since the disease often appears while the child is still premature, must remain so. The neonatal death-rate is also high. Williams estimates the fœtal mortality at 50 per cent., but considers that not more than one-third of the children leave hospital alive. Further, as 70 per cent. of the eclamptic mothers are pregnant for the first time, 400 women die annually with their first child, and the majority, had they lived, would probably have had other children. Eclampsia, therefore, though a relatively rare disease, is of importance to every community in which it occurs. Moreover, if the surviving mothers are incapacitated, either totally or partially, for further child-bearing, its importance is increased, both to the community and to the individual.

Eclampsia is always severe, but the severity of albuminuria of pregnancy varies from a mild albuminuria in the later weeks to "pre-eclampsia." The prognosis for the mother is fairly good under efficient treatment, but for the fœtus, owing to the frequency of premature labours and stillbirths, it remains poor. Albuminuria is extremely common in pregnancy; excluding the physiological albuminuria of labour it occurs in 3·5 per cent. of all pregnant women. If it affects the health of so large a percentage of child-bearing women it is a serious disease, especially if any ill-effects should persist after pregnancy. If it impairs the ability of the woman to bear future healthy, full-time children, it is from the point of view of the race perhaps more serious than eclampsia.

An attempt has therefore been made to find out what health a woman has after suffering from one of the late toxæmias of pregnancy, and how she fares in subsequent pregnancies.

Eclampsia.

A record has been made of 74 women who had eclampsia and recovered in the Royal Maternity Hospital, Edinburgh, not less than three years ago. All those now surviving have been interviewed and examined. At the time of having eclampsia the average age was 27 years; 58 per cent. were primiparæ and three had eclampsia in two pregnancies. Of the 77 pregnancies which ended in eclampsia only 14 were under medical supervision, which in many cases was of a very perfunctory and inadequate kind. In only 8 cases was there no history of warning symptoms, and it is reasonable to suppose that some of the 63 women who had no antenatal care might, under medical supervision, have been prevented from developing eclampsia. Œdema was the commonest and earliest symptom; headache was the next. The average length of gestation was 38 weeks. All the patients had albuminuria and all had convulsions. The fœtal mortality was 38·96 per cent.

Previous Gestations.—Thirty-one of the 74 women were multiparæ when they developed eclampsia, and they had among them 108 gestations. Of these, 83 were normal, 14 ended in miscarriages, and 11 were complicated by albuminuria. That is to say, six women out of 31 had albuminuria in a pregnancy previous to an eclamptic pregnancy.

Deaths.—Three patients have died—one of a second attack of eclampsia and one of pulmonary embolism after a subsequent pregnancy. The cause of the third death could not be ascertained.

---

* Part of a thesis accepted for the degree of M.D. at the University of Edinburgh, 1928.

Result of the Examination of the 71 Surviving Patients.—Thirty-nine women appeared to be in good health. Defects noted in the remainder were as follows: anæmia, 12; chronic constipation, 6; advanced pyorrhœa, 7; bronchitis, 1; enlarged thyroid, 2; myxœdema, 1; enlarged chronically inflamed tonsils, 3; dyspepsia, 1; neurasthenia, 1; hemiplegia (result of cerebral hæmorrhage), 1.

All patients examined are of hospital class and therefore the number who have anæmia is high. Nearly all had some oral sepsis. Special attention was given to the cardiac, renal, and vascular systems. The urine was examined, blood pressure readings were made, the blood-urea was estimated, and the urea-concentration test was done. In two (2·8 per cent.) of the patients a diagnosis of chronic nephritis was made. Ten gave at least one result which was below par in one or other of the tests employed (10·0 per cent.). In five cases (8 per cent.) the tests were incompletely done and no deductions could be drawn. The hearts, arteries, and kidneys of 54 patients (76 per cent.) were healthy.

The following list shows how the 12 patients, A to L, whose renal and cardiovascular systems were judged unsatisfactory, fared in pregnancies subsequent to eclampsia.

Pregnancies Subsequent to Eclampsia.

A. 1 normal. 1 albuminuria. 1 in progress, normal.
B. 1 normal. 3 albuminuria. 3 miscarriages.
C. No subsequent pregnancies.
D. 1 albuminuria.
E. 1 albuminuria.
F. No subsequent pregnancies.
G. 1 albuminuria.
H. 1 miscarriage.
I. No subsequent pregnancies.
J. 1 albuminuria.
K. 1 albuminuria. 1 miscarriage.
L. No subsequent pregnancies.

These patients all complained of vaguely unsatisfactory health.

It has been shown that if a woman has an impaired renal and cardiac vascular system, her post-eclamptic pregnancies will almost certainly be complicated, but that is far from saying that those whose kidneys are satisfactory have had healthy pregnancies after eclampsia.

Subsequent Pregnancies.—Of the 74 women, 42 were pregnant after eclampsia and had between them 67 gestations. Seven of these gestations are in progress; 6 ended in abortions or miscarriages. There have therefore been 54 labours, of which 48 (88·89 per cent.) ended in live births, and 6 in stillbirths. Four of the stillbirths occurred in cases of albuminuria, one in recurrent eclampsia.

Type of Subsequent Gestation.—Of the 42 women who again became pregnant, 17 (40 per cent.) showed late toxæmia in subsequent pregnancies at least once. Of 67 gestations, 10·45 per cent. are in progress, 53·73 per cent. were normal, 26·87 per cent. were complicated by late toxæmia (22·39 per cent. by albuminuria and 4·48 per by cent. eclampsia), and 8·96 per cent. ended in abortions or miscarriages.

Of these 42 women who have been pregnant after eclampsia, 40 have been pregnant again once, 12 twice, 4 three times, and 1 each four, five, six, and seven times.

Of the 40 *first-subsequent* pregnancies, 25 (62·5 per cent.) were normal, 11 (27·5 per cent.) were complicated by albuminuria, and 2 (5 per cent.) by eclampsia, whilst 2 (5 per cent.) ended in abortion or miscarriage.

Of the 12 *second-subsequent* pregnancies, 9 (75 per cent.) were normal, 2 (16·7 per cent.) were complicated by albuminuria, and 1 (8·3 per cent.) ended in miscarriage.

Of the four *third-subsequent* pregnancies, 1 proceeded normally, 1 was complicated by eclampsia, and 2 ended in miscarriage.

The one *fourth-subsequent* pregnancy was complicated by albuminuria, the one *fifth-subsequent* pregnancy was normal, the one *sixth-subsequent* pregnancy was complicated by albuminuria, and the one *seventh-subsequent* pregnancy ended in miscarriage.

Albuminuria of Pregnancy.

A similar investigation was made of 81 patients who had albuminuria of pregnancy, for which they were treated in the Royal Maternity Hospital, Edinburgh, at some time during the same period—i.e., March, 1921, to March, 1926. The average age of the patients when they first developed albuminuria of pregnancy was 29·6 years, and 69·5 per cent.—58 women—were primigravid when they had their first attack.

Previous Pregnancies.—The 23 multiparæ had had 81 previous pregnancies between them before their attack of albuminuria. These were all normal gestations.

Previous Illnesses.—A record was made of any illness from which these women had suffered before their first attack of albuminuria.

	Patients.
Scarlet fever	17
Diphtheria	2
Other exanthemata ..	26
Tuberculosis	3
Bronchitis, pneumonia, pleurisy.	9
Rheumatic fever, chorea	3
Influenza (severe) ..	2
Anæmia	4
Appendicitis	1
Typhoid	2
Syphilis	4
Dysmenorrhœa ..	2

Deaths.—Of the 81 patients, 3 (or almost 5 per cent.) have died, one of a gastric ulcer, another of antepartum and postpartum hæmorrhage—this patient was a 3-para and both previous pregnancies had been complicated by albuminuria—and the third of a cerebral hæmorrhage two months after delivery.

Result of the Examination of the Surviving 78 Patients.—Thirty-three are in good health and seven have poor health. Five of these react unfavourably to the renal and cardiovascular tests; one has active tuberculosis and one refuses to have any examination made. Four patients volunteered the statement that their health "was good except when they were pregnant," at which time they have an indefinite feeling of tiredness from the fourth month onward. All these patients show good renal test results and each has had albuminuria in every pregnancy she has undergone. Thirty-eight patients have indifferent health, which was found to be due to one of the following causes: anæmia, syphilis, heart lesions of rheumatic origin, pituitary deficiency, hyperthyroidism, toxic goitre, dysmenorrhœa, menopausal symptoms, cervicitis, menorrhagia, uterine fibroids, tuberculosis, neurasthenia, bronchitis, advanced pyorrhœa, chronic constipation.

The same attention was given to the cardiac, vascular, and renal systems as in the women who had had eclampsia, and the same tests were done. In six cases a diagnosis of chronic nephritis was made and five more cases gave poor results in at least one test in each case. This result may be compared with that obtained in the eclamptic series:—

	Good results of tests.	Poor results of tests.	Tests incompletely done.
	Per cent.	Per cent.	Per cent.
Eclampsia series ..	76	16·9	8
Albuminuria series ..	81	13	6

Table I. shows how the 11 patients whose renal and cardiovascular test results were considered unsatisfactory fared in their pregnancies.

It will be seen from this table that once an abnormal pregnancy has occurred it has only been followed in one instance—and that a doubtful one—by a normal pregnancy. Patients who fail to react to these tests are almost certain to fail under the test of pregnancy, in this series as in the first. Only two of these 11 cases have had scarlet fever.

As in Series I., therefore, patients with unsatisfactory tests develop toxæmia when pregnant, but, again as in Series I., the fact that the non-gravid, post-toxæmic patient has satisfactory test results does not mean that she will pass normally through a subsequent pregnancy. This is even more obvious in the second series.

Type of "First Abnormal" Pregnancies.—Of the 81 women who were pregnant, 3 miscarried and 53 of the 78 labours were spontaneous. Premature labour occurred in 31 cases. 76 children were born (twin pregnancy occurred thrice in the series), and 18 (i.e., 23·7 per cent.) were stillborn.

Risks to Mother in Subsequent Pregnancy.—Of the 81 mothers, 30 did not become pregnant again after one attack of albuminuria. The remaining 51 women have had altogether 90 subsequent gestations, and 2 (or 3·92 per cent.) have died.

TABLE I.

	Pregnancy—						
	First.	Second.	Third.	Fourth.	Fifth.	Sixth.	Seventh
A	Alb. + +	Alb. + + +	Alb. + +	—	—	—	—
B	Misc.	Alb. + + +	Alb. + +	—	—	—	—
C	Norm.	Norm.	Norm.	Alb.	Misc. c. alb.	Alb. +	—
D	Norm.	Norm.	Norm.	Norm.	Norm.	Alb.	—
E	Alb. +	Alb. + +	Alb. +	Misc. c. alb.	Alb.	—	—
F	Norm.	Alb. + + +	Alb. + + +	Alb. + +	—	—	—
G	? Alb. +	Alb. + +	? Alb. + + +	? Norm.	Alb. + + +	Alb. + + +	Alb. +

I	Alb. +	Alb. + + +	—	—	—	—	—
J	Norm.	Norm.	Norm.	Norm.	Alb. + +	—	—
K	First ten pregnancies, normal; eleventh, miscarriage; twelfth, albuminuria.						

Alb. = Albuminuria. Misc. = Miscarriage. Norm. = Normal.

Risk of Mother Developing Albuminuria Again.—Of the 51 women who became pregnant after one attack of albuminuria, 28 (i.e., 55 per cent.) showed late toxæmia in at least one of their subsequent pregnancies.

Chance of Living Child in a Subsequent Gestation.—Of the 90 subsequent gestations, 6 are in progress and 14 ended in abortion or miscarriage. Of the 70 subsequent labours, 61 terminated in live births and 9 children were stillborn (12·9 per cent.). All cases of stillbirth were associated with albuminuria.

Types of Subsequent Pregnancies.—There have been 90 gestations subsequent to one attack of toxæmia. Of these, 44 were complicated with albuminuria (5 doubtfully), 26 were normal, 14 ended in abortion or miscarriage, and 6 are in progress (5 normally, 1 abnormally). Albuminuria has therefore occurred in 48·89 per cent. of these cases and abortion or miscarriage in 15·56 per cent., while 28·89 per cent. were normal and 6·6 per cent. are in progress.

First-subsequent Pregnancies.—Of these 51 gestations, 21 (41 per cent.) were normal, 24 (47 per cent.) were complicated by albuminuria, 5 ended in abortion or miscarriage, and 1 is in normal progress. In the 45 labours 7 stillbirths occurred, all in association with albuminuria.

Second-subsequent Pregnancies.—Of 22 gestations, 5 (22·5 per cent.) proceeded normally, 10 (45 per cent.) were complicated by albuminuria, 3 are in normal progress, and 4 ended in abortion or miscarriage. Stillbirths occurred in 2 of the 15 labours, both in association with albuminuria.

Third-subsequent Pregnancies.—Of 10 gestations, 1 proceeded normally, 5 were complicated by albuminuria, 3 ended in abortion or miscarriage, and 1 is in normal progress.

Fourth-subsequent Pregnancies.—Of three gestations, one was complicated by albuminuria and one ended in miscarriage. The third is in progress and the patient has albuminuria. Thus only one gestation has terminated in labour, and the child was stillborn.

Fifth-subsequent Pregnancies.—Both gestations were complicated by albuminuria.

Sixth-subsequent Pregnancies.—Of two cases, one ended in miscarriage and one was complicated by albuminuria.

The chance that albuminuria will recur in a subsequent pregnancy is thus seen to be very great. There is a definite predisposition to recurrence after one attack, but in only a small number of those who develop the disease—even of those who develop it several times—is it possible to detect any renal or other impairment when the patient is non-gravid. More than half the gestations subsequent to one attack of albuminuria of pregnancy are abnormal; more than half the women who become pregnant after one attack develop toxæmia again. But the women, like those of Series I., appear and remain well for the most part so long as they are not pregnant.

The figures obtained in the two series may be compared (Table II.).

TABLE II.

Gestations subsequent to first attack of toxæmia.	First series (per cent.).	Second series (per cent.).
Albuminuria	23·39	48·89
Eclampsia	4·48	—
Normal	53·73	28·89
Abortion or miscarriage	8·96	15·56
Gestations in progress	10·45	6·6
Chances of a living child in subsequent gestations (calculated per 100 labours)	88·89	87·1

Comment.

It has been shown that recurrence of late toxæmia is commoner after albuminuria than after eclampsia, but if the two series are taken together 37·9 per cent. of the subsequent gestations are complicated by late toxæmia. As toxæmia of this type occurs in roughly 2·5 per cent. of all pregnant women, there is a definite predisposition to a recurrence after one attack, especially when it is remembered that two-thirds to three-quarters of all toxæmic conditions are found in primiparæ. First pregnancies form from one-quarter to one-fifth of all pregnancies; thus the liability to toxæmia is ten times as great in primiparæ as in multiparæ.

In only a small number of cases can the tendency to develop toxæmia be explained by the presence of nephritis.

The prognosis for a woman who has suffered from eclampsia is—as far as further childbearing goes—better than that for a woman who has had albuminuria.

Among the cases grouped as "albuminuria of pregnancy" various types are found. If these could be differentiated the difference in prognosis would be further stressed. Amongst them are:—

(1) *Cases with an Undoubted Renal Basis.*—Renal impairment is present before, aggravated by, and persists after, pregnancy. Subsequent pregnancies increase the damage. A stillbirth or a miscarriage is the probable end of the pregnancy.

(2) *Cases of Acute Toxæmia.*—The prognosis as regards the future of these cases is the same as that for cases of eclampsia. Could these cases be eliminated from the series of albuminuria of pregnancy the percentage of recurrence of toxæmia in the remainder would be increased.

(3) When cases belonging to the two foregoing groups have been excluded a large number of *cases of unknown origin* remain. During the toxæmic pregnancy the kidney may be apparently greatly damaged, but its capacity for recovery is apparently very great and all signs of disease disappear in the puerperium. No signs appear unless the patient is pregnant again. That is to say, if the criterion of cure is the ability of the individual to remain healthy in a subsequent pregnancy, cure is incomplete. Under the stress of pregnancy the kidney will again show signs of disease. If permanent traces of kidney damage do at length remain in the puerperium these are indistinguishable from ordinary nephritis of the "mixed" type.

The practical outcome of an inquiry such as this is to emphasise the importance of the work of the antenatal and postnatal clinics. While knowledge of the changes which occur in the normal pregnant and puerperal woman are so scanty, knowledge of the toxæmic and post-toxæmic patient can only be incomplete. The benefit to the toxæmic patient herself cannot be overestimated. The incidence of eclampsia is enormously reduced in the presence of antenatal care, though fulminating cases still occur. Mild forms of toxæmia are dealt with and discovered early. A precise knowledge of the time and mode of onset of a toxæmia is invaluable in assessing the dangers of continuing the pregnancy. It is also invaluable in classifying the toxæmia—a classification which can only be made by the postnatal observer.

No accurate ultimate prognosis should be attempted without it, and, if future pregnancy occurs, it is also very valuable information.

The work of the postnatal clinics is no less important. If the return to normal is incomplete, succeeding pregnancies will certainly not be normal and, should pregnancy occur, the patient's chances of bearing a live child are much poorer than those of the healthy woman. If the return to normal is slow it is likely that a subsequent pregnancy will be abnormal. Even if the return to normal is rapid the possibility that the succeeding pregnancy will be toxæmic is greater than in a woman who has had normal pregnancies or who is a healthy primipara. For the furtherance of knowledge, as well as for the benefit of the individual patient, all post- and antenatal information should be laid side by side.

In view of the danger which the toxæmic patient runs the value *of induction of labour must* be emphasised, particularly induction after viability of the child has been reached in a patient who is known to have had one toxæmic pregnancy. In this case the child's interests march with the mother's. Non-interference gives little practical gain and may result in great loss. It is impossible not to think that many cases of albuminuria are carried on foolishly long. An obstetrician should always seriously consider induction in every case of albuminuria which has persisted, despite treatment, for over three weeks, even if the case presents no acute features.

Scheme for Observation of the Toxæmic Case in the Puerperium.

1. Patients should be kept in hospital for at least three weeks postpartum. Regular urinary analysis and blood pressure readings should be made. Before discharge the fundi oculi should be examined and a urea-concentration test done. If any of these results are abnormal blood analysis should be made. The patient's general condition should be noted and a tentative diagnosis made of the type of toxæmia.

2. Three months postpartum the patient should report at the postnatal clinic. Her general condition and her symptoms, if any, should be noted. A urinary analysis and a blood pressure reading should be taken and, in the presence of abnormality, a blood analysis and an ophthalmoscopic examination as well. The diagnosis should be reviewed and corrected if necessary.

3. If the patient has apparently recovered completely at the time of the second examination, she should report again one year *after* delivery. If she shows any abnormality she should report 6 and 12 months after delivery, and each time the same examination should be made. Changes which persist for a year may be regarded as permanent and the patient classified accordingly.

4. In the event of a subsequent pregnancy all postnatal data should be placed, with the diagnosis of the type of toxæmia, in the hands of the attending obstetrician.

5. All patients who have had late toxæmia of pregnancy of any degree should be instructed to report to the antenatal clinic if they know, or suspect, that they are pregnant.

Long-continued observation of the post-toxæmic patient is necessary for an accurate classification of the toxæmia, for an accurate ultimate prognosis in the individual, and for an effective guide to treatment in future pregnancies.

Summary.

1. About a quarter of the pregnancies which occur after eclampsia are complicated by some degree of toxæmia. 2. Almost half the pregnancies which occur after albuminuria are complicated by some degree of toxæmia. 3. The earlier albuminuria begins in pregnancy and the longer it persists the more likely is it to cause renal damage and to recur in a future pregnancy. 4. Recurrence of toxæmia occurs in the absence of any detectable trace of renal impairment. 5. If traces of renal damage are absent, and if patients do not become pregnant they remain in good health.

I am much indebted to the medical staff of the Maternity Hospital, Edinburgh, for access to records of cases, and for permission to examine patients at the hospital.

THE CLINICAL PICTURE PRODUCED BY
SUBACUTE MENINGOCOCCAL SEPTICÆMIA.

BY C. LAWSON STOTE, M.B. CAMB., M.R.C.S. ENG.

RECENT bacteriological investigations have shown that meningococcal meningitis may often be preceded or accompanied by a septicæmia of relatively short duration and of secondary importance. On the other hand, primary meningococcal septicæmia may occur with or without meningeal involvement, the septicæmia being the striking clinical feature. These latter cases may be classified in the following way:

1. *Acute Septicæmia.*—Localisation of meningococci in the meninges occurs a few days after the onset of septicæmic symptoms. The onset is sudden, there are very marked septic symptoms, great prostration, and usually a petechial rash. Death occurs in a few hours or a few days. Meningococci may be cultured from the blood. Andrewes in 1906 was one of the first to describe a case of this type.

2. *Subacute Septicæmia.*—This group includes cases of meningococcal septicæmia which run a course of from one to several months' duration. They may be further subdivided into: (*a*) those cases which eventually show meningeal involvement; (*b*) those associated with infective endocarditis; (*c*) those exhibiting the features of a pure septicæmia without metastases.

It is the clinical picture presented by this second group of subacute cases that I wish to describe, particularly those which show a pure septicæmia without metastases. The reason for treating these cases separately is that they all reveal themselves by a well-differentiated clinical picture, which renders their diagnosis comparatively easy. The condition has not received much attention in this country, and though it is probably rare it seems likely that the majority of cases are unrecognised.

Rolleston, in an extensive survey of all types of meningococcal infections, briefly shows that "intermittent meningococcic fever" due to septicæmia may (*a*) last for weeks without any meningitic symptoms, or (*b*) may follow meningitis, or (*c*) show transient meningitic symptoms, or (*d*) terminate in meningitis, but states that a correct diagnosis is seldom made in the absence of meningitic symptoms.

Graves, Dulaney, and Michelson, in publishing a case of chronic septicæmia in which meningococci were present in the blood and cerebro-spinal fluid and which recovered after about three months' pyrexia, state that 13 cases of subacute or chronic meningococcal septicæmia have been described in the American literature. Of these, three, ending in death, had associated endocarditis (those of Warfield and Walker, Cecil and Soper, and Dock); four had septicæmia with a secondary meningitis for a varying length of time and recovered, while the remaining six had septicæmia without involvement of the heart or meninges. These last, which were described respectively by Bray, Herrick, Morgan, Bloedorn, Neergaard and Marlow, all had intermittent temperatures for two to five months, but eventually became quite well. The authors state that subacute or chronic meningococcal septicæmia shows a triad of symptoms consisting of intermittent fevers with rigors, skin eruptions, and arthropathies. The eruptions come in crops with a rise in temperature, and may be either purpuric, macular, or papular.

The joint pains are usually slight, without physical signs, but there may rarely be the formation of fluid.

In March, 1928, O. Herman and M. Eifschitz recorded a case in a man aged 30 who had remittent fever, erythematous eruptions on the limbs, no physical signs, and a relatively good general condition. A pure culture of meningococci was obtained from the blood, and the man made a spontaneous recovery. These authors quote Friedemann and Deicher as stating that the characteristic features of meningococcal septicæmia are:

1. Nasal, pharyngeal, or bronchial catarrh.
2. Fever, remittent at first and then irregular, lasting from one to several months.
3. Erythematous eruptions.
4. Protracted course without physical signs.
5. A relatively good general condition.

G. Mahieu in 1928 collected seven cases which appeared to be subacute meningococcal septicæmia. In three of these meningococci were present in the blood and there was no meningeal involvement, in one case the organisms were recovered both from the blood and the cerebro-spinal fluid; and in two the blood culture was negative, but the organisms were obtained from the cerebro-spinal fluid. In the seventh case no organisms were isolated but the symptoms were analogous to those of the other six. All these cases showed remittent temperature running a subacute course (from two to five months), accompanied by joint and muscular pains without physical signs, and erythematous eruptions, especially on the limbs and face. All the cases made a complete recovery.

Two New Cases.

I wish to describe two cases of subacute meningococcal septicæmia I had under my care at the London Hospital while I was house physician. By a remarkable coincidence I admitted both cases from the receiving room on the same day, and as they were in the same ward throughout their illness I had a unique opportunity of noting the similarity of the two. Both were boys; they came from entirely different neighbourhoods of London and had not been associated with each other outside. There was no epidemic of cerebro-spinal meningitis at the time. I am greatly indebted to Dr. Robert Hutchison for giving me permission to publish these two cases, and also to Dr. G. T. Western for allowing me to quote the results of the blood cultures.

CASE 1.—A schoolboy, aged 7, was admitted to the London Hospital on Nov. 17th, 1927.

History.—His mother said he had been quite well until five weeks before, when he had gone off his food and begun to feel unwell. At the same time a rash had appeared on his hands, arms, legs, and face. This had consisted of scattered, non-irritating spots, none of which had appeared on the trunk. Some spots had faded, while new ones had made their appearance in crops ever since the onset of the illness. All this while (five weeks) he had been kept in bed and the doctor stated that he had had a swinging temperature, up to 103° F. at night. Pains had been present all the time in the large joints of the arms and legs. These had never been severe, and flitted about from joint to joint, rarely being more than a day in any one joint. The joints had never been red or swollen. He had vomited after food every day until a week before, but not since. These had been ordinary food vomits. The bowels were regular and there was no diarrhœa. At no time were there any headaches, sore-throat, backache, or earache. There had been no discharge from the eyes or nose, and no shivering attacks were noticed. The only previous illness he had had was measles when 2 years old. The mother and father were alive and healthy. There were five other children alive and well, and three had died, two of pneumonia and one of scalds.

On admission he appeared as a slightly-built little boy, somewhat pale but not anæmic or under-nourished. The tongue was moist and clean and the throat clear. The eyes were not inflamed. There was no evidence of nasal or bronchial catarrh. There was a pink papular eruption copious on the face, arms, and legs, sparse on the buttocks and back, and absent from the chest and abdomen. Each papule consisted of a uniformly coloured, slightly raised, rose-pink area, varying in size from that of a pin's head to that of a threepenny piece. A very few had punctate purpuric centres. They were not irritating. There was no pain or swelling of any joint. The spleen was not palpable and nothing abnormal was found in the abdomen, heart, or lungs. Nothing abnormal was found on examination of the central nervous system and there was no clinical suggestion of meningeal infection.

Course of Illness.—The temperature was 100·5° F. on admission. For the next ten weeks the temperature was swinging between normal and 102° to 103°. The highest temperature usually occurred in the evening, but occasionally in the morning. Every now and again a period varying between one and four days would pass without pyrexia. During the following three weeks (Jan. 20th to Feb. 15th) there was an occasional rise up to 100° F. After this the temperature settled. The pulse-rate throughout remained at just over 100 per minute, and the respiration-rate at a little over 20.

Throughout the period of pyrexia the patient appeared remarkably well, considering the temperature he was running. He would sit up in bed all day long, play with his toys, laugh and joke with the other boys in the ward, and sleep and eat well. It was only for a few hours every second day or so that he would appear tired and rather ill, and would lie down, become quiet, and lose interest. These periods would always coincide with a "peak" in the temperature chart and usually with the complaint of joint pains, either in the legs or arms. The day following would usually yield a fresh crop of spots. The rash had the same characteristic throughout and never completely vanished until the temperature finally settled. One crop of papules would start to fade three or four days after its appearance and then be succeeded by a second. The rash was chiefly confined to the limbs and face, was sparse on the buttocks and back, and never appeared on the chest or abdomen. At times a very few of the papules would show a definite punctate purpuric centre. The spleen became just palpable at the beginning of December (the eighth week of the disease). The edge could be felt quite distinctly for a day or two, but was not felt again after this. The heart sounds remained normal throughout. There were no signs at all indicating any meningeal infection. The slight headaches complained of at times were never severe. Joint pains would come and go from day to day. One of the large joints of the arms or legs would be affected for a day at a time, causing pain on movement, but no swelling or redness. The pains were never very severe and would not keep him awake at night. They disappeared with the fall of temperature.

When he was discharged from hospital on May 15th, 1928, there were no physical signs of disease and he appeared quite well in himself.

The following *special investigations* were undertaken while he was in hospital. The blood culture on Nov. 17th and Dec. 31st, 1927, and on Jan. 10th and 24th, 1928, yielded a Gram-negative diplococcus which from all its characteristics appeared to be the meningococcus. It was agglutinated by meningococcal serum, group 4. The blood culture was sterile on Feb. 26th, after the patient had been afebrile for 14 days. Lumbar puncture was performed on Nov. 30th. The fluid was clear, not under excessive pressure, and on microscopic examination showed no cells or organisms. There was no excess of protein and the cultures were sterile.

A blood count on Nov. 17th showed: 4,800,000 erythrocytes and 6850 leucocytes per c.mm.; hæmoglobin, 72 per cent., and a colour-index of 0·75. A differential count of the white cells showed: polymorphonuclear leucocytes, 68·5 per cent.; small lymphocytes, 30 per cent.; large lymphocytes, 8 per cent.; and large hyalines, 3 per cent. The Wassermann reaction in the blood on Nov. 23rd was negative. The urine remained clear throughout.

An autogenous vaccine was prepared from the organisms from the blood culture and was given as follows: Dec. 16th, 25 minims; 22nd, 25 minims; 30th, 50 minims; Jan. 14th, 100 minims. No reaction followed any of the injections.

CASE 2.—A shop errand boy, aged 15, was admitted to the London Hospital on Nov. 17th, 1927.

History.—For the preceding two months he had had a rash which had first appeared on his chest and had spread after one week to his limbs. It had gradually cleared from the body, but remained on the limbs. It had consisted of rose-red, non-irritating spots up to 1 cm. in diameter. He had not felt well in himself but had remained at work until one week before, when he had had a sore-throat and been in bed for one day. Four days earlier he had begun to have pains, moving from joint to joint, starting in the ankles, and then going to the knees and wrists. There had been no swelling of the affected joints. His appetite had remained good throughout and his bowels normally opened. There was no history of any discharge from the ears, nose, or penis, and no headaches or shivering attacks. He had had "fits" when a baby up to the age of 3 years. From this age onwards until he was 9 years old his eyes had given him trouble, for which he had attended a hospital and had injections for treatment. His mother and father were alive and healthy and there were five other healthy children.

On admission he appeared a rather pale, definitely ill-nourished lad, with a white-coated tongue. Each eye showed scars of central corneal ulcers, and there was a certain amount of catarrhal conjunctivitis. There was no evidence of congenital syphilis. The tonsils were slightly enlarged but not infected. There was a rash on the arms, legs, and thighs consisting of a sparse, diffuse papular eruption, the spots being slightly raised rose-pink papules up to 1 cm. in diameter. None was purpuric and they were not irritating or painful. There were no spots on the face or trunk. There was pain on movement of the knees, ankles, and wrists, but no swelling or redness. There were no rheumatic nodules. The spleen was not palpable, and there was nothing abnormal in the abdomen, heart, or lungs.

Course of Illness.—He had a temperature of 101° F. on admission, but this came down within three days and remained normal for four days. For the following four days he had a swinging temperature—98° F. in morning and up to 103° F. at night—culminating in a rigor on the evening of the tenth day after admission. There was a swinging temperature for the next ten days (up to 102·6° F. at night), and it then settled to normal at the beginning of the fourth week after admission (the twelfth week of the disease). There was no further pyrexia. The pulse-rate varied between 70 and 86, and the respirations averaged 20 per minute throughout. The rash on the face and limbs disappeared within three or four days with the fall of temperature, and at this time he appeared quite well in himself. Within a week increasing temperature at night was accompanied by a fresh crop of papules on the limbs and face and a few on the buttocks and back. The rigor on the twelfth day was followed by a third crop of papules—the last to appear—and these faded gradually and disappeared within ten days. Throughout the pyrexial period the patient remained well in himself, would sit up in bed, amuse himself by drawing, and talk and joke with the others in the ward. A few hours before and after the rigor he was quiet, went off his food, and lay listlessly in bed. The joint pains that were present on admission disappeared in three to four days and no definite joint pains were noticed after this. On Dec. 6th (the twentieth day after admission) he had quite a severe backache which lasted all day and radiated downwards to both thighs. There was some pain on movement of either hip-joint. The heart remained clear throughout and the spleen was never palpable. A few days before he was discharged he developed a phlyctenular ulcer at the edge of the left cornea. Otherwise he was well.

No treatment by drugs or vaccines was attempted.

The following *investigations* were carried out.

The blood culture on Nov. 25th, 1927, yielded a Gram-negative diplococcus identical with that obtained from the first case. On Dec. 20th (after the patient had been afebrile for ten days) the cultures were sterile.

On Nov. 30th lumbar puncture gave a clear fluid, not under pressure. It contained no cells or organisms and the cultures were sterile.

A blood count on Nov. 25th showed 4,900,000 erythrocytes; a hæmoglobin percentage of 78; a colour-index of 0·79; and 12,400 white cells; of which 66 per cent. were polymorphonuclear leucocytes, 21 per cent. were small lymphocytes, 6 per cent. were large lymphocytes, 6 per cent. were large hyaline, and 1 per cent. were eosinophils. The Wassermann reaction on Nov. 22nd was negative. The urine was clear throughout the illness.

The symptoms and physical signs in the two cases were closely similar in all important respects. Also, the course which the disease pursued was almost identical in both boys. In both the blood culture grew typical meningococci during the height of the disease, and in both the cultures became sterile as the disease subsided. In neither was there any alteration in the cerebro-spinal fluid, nor were any organisms found in it, while in no single symptom was meningeal involvement suggested. There was nothing pointing to any other infection or localisation of disease. It is thus reasonable to suppose that the symptoms and physical signs present were due directly to meningococcal septicæmia and to this alone.

The Clinical Picture.

The signs and symptoms in each case formed a clinical picture different in many essential respects from that shown by other septicæmias. As there was no involvement of the central nervous system, neither clinically nor bacteriologically, and no other signs usually associated with the ordinary meningococcal infection—i.e., meningitis—one is justified in regarding this condition of subacute meningococcal septicæmia as a well-differentiated disease, running a definite course. Arguing from the close similarity of these two cases, one obtains the following picture of the condition.

The onset is insidious, and the first indication that a grave disorder is present may be the swinging temperature, which is remittent in character, with a daily variation of 5 or 6 degrees Fahrenheit or less. Rigors may occur. Apparently the temperature continues for a few months—in one case it was three months, and in the other four and a half—finally, becoming normal as the other symptoms subside. Probably the most striking feature is the relatively very good general condition of the patient. With such a temperature one would expect the general condition to be definitely bad, but both these patients were bright, lively, and cheerful throughout, and there was no "ill-look" about them. The rash seems to be fairly characteristic, but in some respects resembles erythema nodosum. The distribution is peculiar, being almost confined to the limbs and face. The spots are scattered, rose-red papules, appearing in crops usually corresponding to extra high "peaks" in the temperature chart. They are non-irritating and disappear without leaving any discoloration. The joint pains are transitory, not very severe, and unaccompanied by any physical signs in the joints. They occur in any of the large joints of the limbs, passing from one joint to another and not remaining more than a few days in any one joint.

In all these particulars these two cases exhibit similar symptoms and follow similar clinical courses to the cases of subacute meningococcal septicæmia recorded by other observers.

Conclusions.

1. Subacute meningococcal septicæmia, when uncomplicated by metastases, gives a clinical picture which is peculiar to the condition, forming a definite clinical syndrome.

2. It is characterised by: (*a*) remittent fever, lasting from a few weeks to several months; (*b*) a rash, consisting of small papules which come out in crops, especially on the limbs and face; (*c*) joint pains, moving from joint to joint, appearing with a rise of temperature and disappearing during defervescence; (*d*) absence of physical signs; (*e*) relatively extremely good general condition of the patient; (*f*) an excellent prognosis.

3. Meningeal infection need not occur during a meningococcal septicæmia of this type.

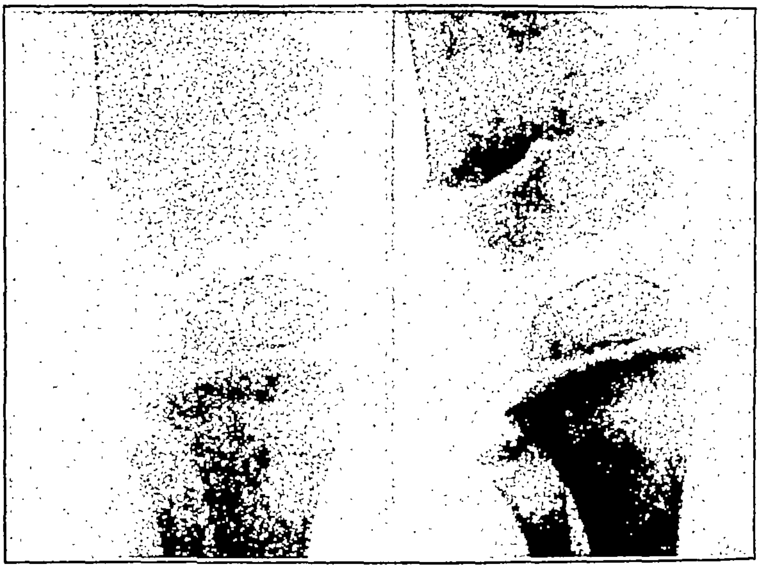
ST. MARY'S HOSPITAL.—It is pointed out in the annual report that the recent extension has necessitated the employment of a larger number of nurses, and that since there is no room for them they have been temporarily housed in the isolation ward. The need of additional accommodation for the nursing staff is consequently urgent. There are now 303 available beds, 263 of which during the past year were constantly occupied. The 4575 in-patients stayed an average of 22 days, and cost £14 10*s.* 0*d.*; there were 40,440 new out-patients, who cost 6*s.* 1*d.* each. The tuberculosis dispensary continued to do good work; there were 231 new cases.

No medicinal or other measures were employed, with the exception of an occasional mild laxative medicine (syrup of figs) to counteract the slightly constipating tendency of the dietary. For the first few days little food was taken owing to gastric disorder. The extreme muscular feebleness of the child precluded the necessity of any measures being required to ensure rest to the limbs. The radiographic appearances were those of advanced florid rickets.

Within a fortnight the improvement in the general condition of the child was striking, this being associated with a notable improvement in the X ray appearances of the limbs. At the end of six weeks, when the radiographic appearances of the joints were almost normal, additional measures were employed in the form of splints and massage to keep the child at rest and favour correction of the pronounced curvature of the limbs. Complete elimination of the severe curvature was not effected, and it is probable, in view of the unfavourable environment of the child, that this will not be obtained without surgical assistance at a later date. A remarkable feature of the case was the coincident improvement which took place in the mental development of the child. From being unable or unwilling to speak and being generally inanimate, the power of speech, an interest in his surroundings, and all the mental traits of the average child manifested themselves. This improvement in the psychological state did not noticeably develop until after three weeks' treatment.

FIG. 5. FIG. 6.

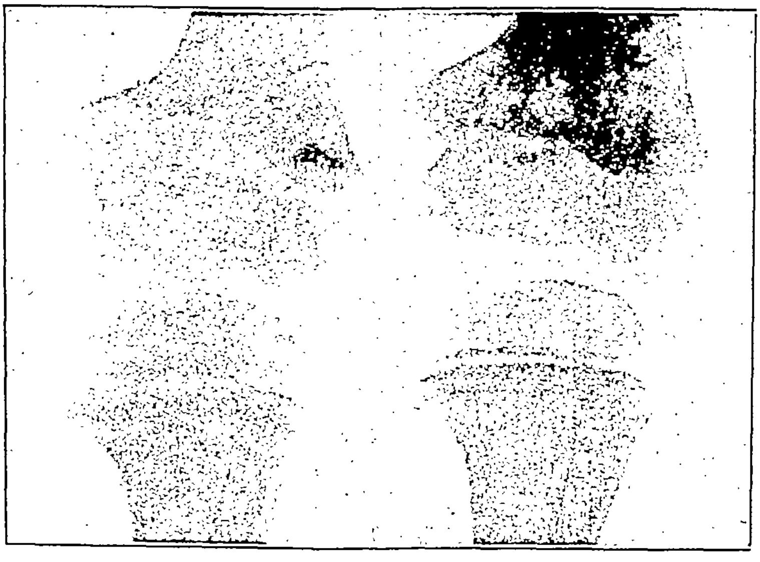


Case of rickets before and after one month's treatment with irradiated milk. The change from the very indefinite and irregular metaphysis to the normal regular dense line is well shown.

CASE 2.—This is recorded as one of four cases selected as specially suitable for the investigation. He had been an in-patient in the Victoria Home for five months for the treatment of rickets, but had proved unusually refractory to treatment, the general condition of the child and the radiographic appearances of the joints being still unsatisfactory, and the lesion still active. Besides a careful antirachitic dietary, which included 18 oz. of high-grade milk and orange-juice daily, a course of various special antirachitic remedies had been given. This included irradiated ergosterol (95 tablets), ostelin (8 oz.), exposure to ultraviolet rays, &c. All medicinal and other special measures of treatment were stopped, the dietary in use was continued with the exception that 6 oz. of irradiated milk of Certified standard replaced 6 oz. of the Grade A (tuberculin tested) milk ordinarily supplied to the home.

Under this regimen an improvement in the clinical condition was striking and rapid. The favourable influence of the treatment is indicated in Figs. 7 and 8. Fig. 7 illustrates the condition of the wrists after five months' indoor treatment, before the administration of the irradiated milk was begun. Fig. 8 depicts the same joint after four weeks' treatment with irradiated milk. The radiographic appearances were then practically normal, the clinical condition having proportionately improved.

FIG. 3. FIG. 4.



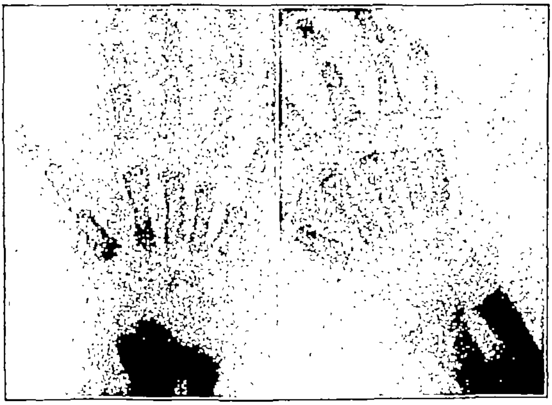
Case of florid rickets. Note the wide epiphyseal lines with irregular striation throughout the cartilage. There is also typical "flaring" of the metaphysis with irregularity of the edge. Fig. 4 shows the condition of the same bones after one month's treatment with irradiated milk. Note the rapid approximation to the appearance of a normal joint.

It is noteworthy that this recovery (and similarly in the other three cases) was effected merely by substituting 12 pints of irradiated milk for 12 pints of milk of similar quality unirradiated, all medicinal and other special therapeutic measures being withheld. It is important to note that the cost of the special irradiated medicinal products (excluding ultra-violet rays) administered in the previous five months—with very restricted success—would be, at retail rates, approximately 18s. As our experience leads us to believe that there could be no justification for the price of irradiated milk exceeding that of unirradiated by more than 1*d.* per pint, the total cost of the special treatment—and of the recovery—over the four weeks' period was 1s. On the economic side, therefore, the advantage lies markedly on the side of treatment by irradiated milk.

A Word of Caution.

A word of caution is necessary about the use of irradiated milk. It is essential, in view of its profound influence on the growing bones, to keep in view the possibility of overstimulation leading to premature ossification. This danger can be easily avoided. With our present limited knowledge it is, in our opinion, essential that irradiated milk should not be considered a complete substitute for good fresh milk. In a series of adult subjects to whom we administered the milk to the extent of 8 pints daily over a period of six weeks no untoward symptom of any kind was observed. In view, however, of various experimental results that have been recorded in animals from the use of highly irradiated products, in the form of abnormal calcification in the cardiovascular and renal systems, the milk should be used with care and discrimination. It may be accepted, beyond any possibility of doubt, that the recent discovery of the value of properly irradiated milk is one of very far-reaching importance alike to the practitioner, the physiologist, biologist, and the student of nutrition generally. The question of the standard of irradiation, and the possibilities of its application in conditions other than rickets, may be briefly referred to.

FIG. 7. FIG. 8.



Wrist of child aged 3. After five months' hospital treatment, rachitic changes are still present in Fig. 7. Note "cupping" of the ulna. In Fig. 8, after one month's treatment with irradiated milk, no rachitic changes are detectable.

Standards.

In this country irradiated milk can only be sold under license from the patent holders. Under this arrangement the licensees agree that "their irradiated milk shall not contain less than two (2) ostelin (vitamin D) units per gramme of butter-fat as determined by the pH drop test under conditions laid down in the papers by Jephcott and Bacharbach (*Biochem. Jour.*, 1926, xx., 1351, and 1928, xxii., 60), or alternatively eight (8) Pharmaceutical Society's units per gramme of butter-fat as determined by the line test employed by the Pharmaceutical Society." With fuller knowledge time may show that these tests may require modification. We have at present no assurance that the butter-fat supplies a complete and reliable guide. The material point for the profession and the public at the present time, however, is the fact that under the existing standards milk can be successfully irradiated so as to impart to it a very valuable additional therapeutic property in the prophylaxis and cure of rickets. A further question that naturally arises is the possibility of irradiated milk proving of value in conditions other than rickets. While no authoritative statements can be made on this subject it may be useful to indicate some directions in which evidence may reasonably be looked for.

Irradiated Milk in the Treatment of Other Disorders.

In the past few months a series of observations have been made on the feeding of children in the Craiglockhart Parochial Hospital, Edinburgh, under the direction of Dr. R. W. Dawson, resident physician. The cases observed showed the very severe malnutrition commonly seen in patients in these institutions. The results, more especially in the case of children over one year old, have been very gratifying, the gain in weight and improvement in the general condition of the children having been very satisfactory. The possible value of irradiated milk in the treatment of various disorders of pregnancy and lactation, associated with derangements in calcium metabolism, has been referred to in medical literature, but adequate data on the subject are still lacking. Through the kindness of Mr. F. E. Jardine, surgeon in charge of the special sanatorium under Edinburgh Corporation for the treatment of tuberculosis and other disorders of an orthopædic classification, we have had an opportunity of testing the effects of irradiated milk in a series of four cases of advanced tuberculous disease of the knee-joint of three to five years' duration. The favourable results obtained have been very striking. These amply justify the recommendation that a thorough and prolonged investigation should be made in this direction. To this end it is, in our opinion, desirable that the whole subject should be investigated under the ægis of a specially appointed scientific body, whose opinions and recommendations, on scientific and clinical questions, would commend themselves to the profession.

Conclusions.

1. The claims of numerous German writers concerning the value of irradiated milk in the prevention and cure of rickets are amply confirmed. 2. Irradiated milk should not be regarded as a complete substitute for good fresh untreated milk. 3. In rickets, between 2 and 5 years of age, excellent results have followed its use when the milk has been used in strengths varying from 1 part irradiated to 2 parts unirradiated, up to equal parts of the two preparations. 4. The cure of the disease is established more quickly, effectively, and economically by the use of irradiated milk than by various irradiated commercial preparations. 5. There are indications that irradiated milk may prove of outstanding value in the treatment of certain disorders other than rickets—notably *disorders incidental to pregnancy and lactation, the* climacteric, malnutrition, injuries and surgical diseases of bone, and certain forms of tuberculosis. 6. There is need for the establishment in this country of a scientific body to initiate and direct the work, both on its strictly scientific and clinical sides, called for by these new facts about nutrition, and the influence of ultra-violet rays upon it.

We have pleasure in expressing our indebtedness to Dr. Woodburn Morison, of the Radiological Department of the Royal Infirmary, Edinburgh, for his cordial coöperation and assistance; also to the British Hanovia *Quartz Lamp Co. (Scholl apparatus), and Food Irradiation Co. (Scheidt apparatus), for their courtesy in putting apparatus at our disposal for the investigation.

THE board of management of Birmingham General Hospital have accepted the offer of an anonymous donor to establish a studentship in diabetic research of the value of £250 a year. The studentship will be held in connexion with the hospital's diabetic clinic.

Clinical and Laboratory Notes.

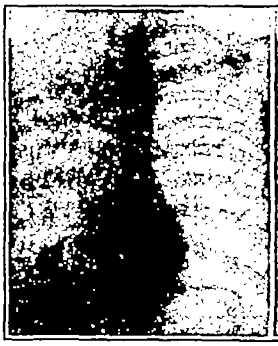
A CASE OF ADENOCARCINOMA OF BRONCHUS.

By L. S. T. Burrell, M.D., F.R.C.P. Lond.,
PHYSICIAN TO THE ROYAL FREE HOSPITAL AND TO BROMPTON HOSPITAL FOR CONSUMPTION.

The patient, a man of 29, complained of pain on the right side of the chest, dyspnœa, cough, and sputum which was often blood-stained.

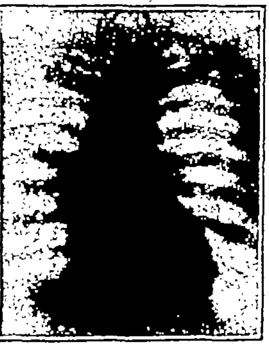
He dated the symptoms from an accident in November, 1928, when he broke a tooth, and it was thought that he might have a piece of broken tooth in a bronchus. On examination in April, 1929, no breath sounds were heard on the right side of the chest which was found to be completely dull, and the heart was slightly displaced towards the right side. A diagnosis of collapse was made, and this was confirmed by radiography (Fig. 1); but as no foreign body was seen the presence of a tumour was suspected. In May the patient was examined through a bronchoscope by Mr. V. E. Negus at King's College Hospital, and a red, rounded, smooth mass was seen projecting from the posterior wall of the right bronchus just above the orifice of the upper lobe bronchus into which it was sucked during inspiration. A lot of fœtid pus was aspirated, and the tubes cleaned in order to make subsequent operation more satisfactory.

FIG. 1.



Collapse of right lung. Heart slightly displaced to the right.

FIG. 2.



The right lung has now re-expanded and the heart has returned to its normal position.

A few days later Mr. Negus again passed a bronchoscope, and painted the growth with cocaine and adrenalin. It now appeared as a mere bulge from the bronchial wall, but had a definite pedicle, and he was able to remove it with biting forceps, leaving the base as a small excoriated area. It was then possible to see clearly down the right lower lobe bronchus. The tumour looked like a soft fibroma, but on section it proved to be adenocarcinoma.

Radiographic examination ten days after the operation showed partial re-expansion of the right lung. The note on percussion was still impaired on the right side, but it was not dull and air could be heard entering the lung. The patient left hospital much improved and had very little dyspnœa. Fig. 2 shows the condition at the end of July, 1929, ten weeks after the operation. The patient was then free from all symptoms and felt perfectly well.

This case is similar to the one I published in THE LANCET (1927, ii., 1180), but in that patient the tumour was a simple fibroma, and when I last heard from her in May, 1929, she was quite well and had had no further symptoms since the tumour was removed. In the present case it is probable that the carcinoma will spread, although it is possible that the whole tumour has been removed.

The patient was referred to me by Dr. Malcolm Hutton, of Stamford, and I am indebted to him for permission to publish this paper, and to Dr. Ulysses Williams for the skiagrams.

A CASE OF CICATRICIAL STENOSIS OF THE ŒSOPHAGUS.

By Kenneth Heritage, M.B., F.R.C.S. Eng.,
LATE RESIDENT SURGICAL OFFICER, ANCOATS HOSPITAL; RESIDENT MEDICAL OFFICER, MILLER HOSPITAL.

The following case illustrates the importance of œsophagoscopy as a means of diagnosis in œsophageal obstruction.

A married woman, aged 42, first attended Ancoats Hospital, Manchester, on March 9th, 1929, with a history of six days' complete œsophageal obstruction; she was unable to retain even small quantities of water. For two years previously she had suffered from progressive difficulty in swallowing—solids, meat, &c., having to be minced for her. Being of a rather nervous disposition this had been treated for a time by her doctor as a case of hysteria.

On examination I found an anæmic wasted woman, very weak, and scarcely able to walk. Her weight was 6 st. 2 lb., which was 2 st. less than it had been six months previously. Fluids and solids were returned unchanged from the œsophagus. Routine screening of the chest excluded thoracic neoplasm and aneurysm, and a barium meal revealed complete œsophageal obstruction at the level of the eighth thoracic vertebra. The Wassermann reaction was negative.

Before œsophagoscopy the patient had denied the possibility of having swallowed corrosives, but on going into the matter further with the relatives afterwards it was discovered that, at the age of 3, she had swallowed "lye" (caustic soda) in mistake for ginger-beer.

After combating the patient's dehydrated condition with subcutaneous and rectal saline I passed an œsophagoscope under general anæsthesia, and found, 20 cm. from the edentulous gums, a hard fibrous lip surmounting a pale white annular stricture. No foreign body was present. Complete obstruction was due to stenosis alone. With difficulty a filiform bougie was introduced under direct vision, and left in situ for several hours. The stricture was subsequently dilated with graduated gum-elastic bougies under direct vision, at three sittings under anæsthesia, and was shown to be solitary. Later, the patient having become accustomed to instrumentation, it was found preferable to pass the œsophagoscope without anæsthesia, by the method described by Abel,[1] and this has proved a good method of examination and treatment of this condition. She is now able to swallow anything and is rapidly gaining weight in consequence.

The case is unusual in view of the long period (37 years) between swallowing caustic in infancy—an event forgotten by the patient—and the onset of definite dysphagia two years ago. The complete nature of the obstruction when first seen is also noteworthy.

Treatment by gradual dilatation under direct vision through an œsophagoscope passed under local, or without, anæsthesia, forms in my opinion the ideal method of maintaining patency in the case of simple œsophageal stricture. "Blind bouginage" can only be condemned by the dictum of Trousseau, that "sooner or later all cases of stricture of the œsophagus die of the bougie." Other methods, such as those of Plummer and Tucker, demand the presence of a gastrostomy over a prolonged period in a patient who is able to swallow the thread guide.

I am indebted to Mr. F. Holt Diggle, from whose clinic this case is reported.

CHRONIC PARASITIC FUNICULITIS IN EGYPT.

By Dr. M. F. Sorour,
ASSISTANT PROFESSOR OF PATHOLOGY, FACULTY OF MEDICINE, CAIRO.

Ten years' experience in examining pathological material sent from Government hospitals all over Egypt has shown that chronic nodular masses, of varying size, are not uncommon lesions in the spermatic cords of the Egyptian fellaheen (peasants).

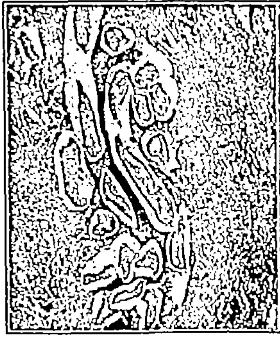
---

[1] Abel, A. L.: Œsophageal Obstruction, London, 1929, p. 39.
[2] Sewell, Lindley: THE LANCET, 1928, i., 1008.

These nodules vary in size from a hazel-nut to a pigeon's egg, and are, as a rule, painless, or only slightly tender. Two varieties of this condition have been met with, due respectively to two different parasites—namely, filaria and bilharzia.

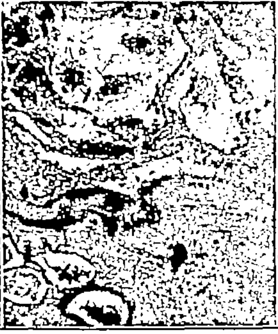
(1) *Chronic Filarial Funiculitis.*—For many years I had received spermatic cord nodules, which, in sections, showed: Chronic fibrosis, with very heavy eosinophil cell infiltration, enclosing thickened walled blood-vessels, whose lumens were narrowed, or completely obliterated, by organised thrombosis. I named these lesions "chronic eosinophilic funiculitis"; and although no bilharzia, ova, or worms had been found in them, I suspected a worm infection. In 1927 I received a spermatic cord nodule from the Government hospital at Zagazig, which, on section, disclosed, besides the histological changes above described, a large lymphatic vessel cut very obliquely, show layers of endothelial proliferation, containing many multinucleated cells. In its lumen was an intact filaria worm, cut in many places and directions. In the very oblique, almost longitudinal, sections of the worm were ova and embryos.

1



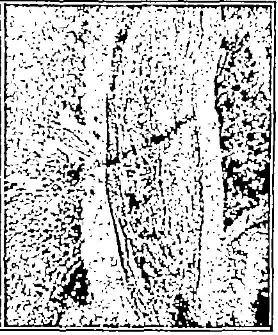
Lymphatic vessel containing filaria worms, cut in different situations and directions, and surrounded by a cellular mass.

2



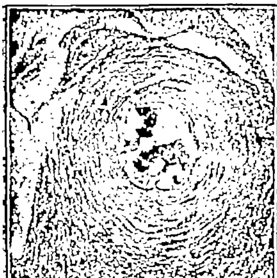
Filaria worms in lymphatics from another case.

3



High magnification of part of filaria worm, showing embryos inside the mother worm.

4

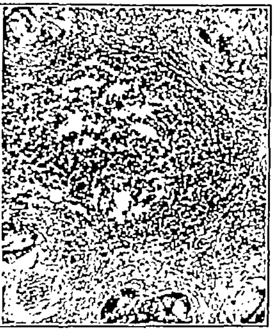


Remains of degenerated worm inside fibrosed, obliterated lymph vessel, in a chronic case.

5

Heavy eosinophil cell infiltration in tissue of a nodule from an early case of filarial funiculitis.

6



Bilharzial funiculitis showing heavy eosinophil cell infiltration, and many bilharziomata with ova and giant cells.

The worm was surrounded by a heavy cellular mass of endothelial cells, many polynucleated cells, and eosinophil cells. At one end of the obliquely cut lymphatic were filaria embryos lying intermixed with the cellular elements surrounding the worm. In serial sections the same lymph vessel in its part beyond the worm was occupied by similar cellular contents much intermingled with filaria embryos apparently on their way to the blood stream. The long-standing suspicion thus confirmed, I went back to the old collected and preserved spermatic cord eosinophilic nodules, and on serial sectioning found, in each case, direct evidence of filarial infection, either in the form of intact filaria worm; or of degenerated worm inside a fibrosed lymph vessel; or of lymph vessels obliterated by endothelial and eosinophil cells with filaria embryos amongst them; or of calcified remains of the worm. These findings established, for the first time, the existence of *chronic filarial funiculitis* in Egypt. I think that the acute endemic funiculitis which occurs in Egypt and frequently goes on to suppuration is engrafted on a chronic filarial lesion. The analogy is with the acute febrile inflammatory attacks which occur repeatedly in the course of chronic elephantiasis of leg, scrotum, and breast.

(2) *Bilharzial Funiculitis.*—This, the second type of parasitic funiculitis met with in Egypt, is due to

lateral spined, or to terminal spined, or to both kinds of ova lying in the tissues of the spermatic cord. The lesions are characterised by round, oval, or cord-like hard fibrous tumours, easily shelled out from the surrounding tissue. Histologically they consist of fibrous tissue densely infiltrated with eosinophil cells, and with many bilharziomata embedded in the mass. The bilharziomata are small, tubercle-like structures, consisting, when recent, of one or two central bilharzia ova, surrounded immediately by huge giant cells, and peripherally by layers of large endothelioid cells. In older bilharzioma the outer endothelioid layers are replaced by hyaline fibrous tissue, which may increase concentrically until the whole is a mass of whorls of hyaline fibrous tissue, with the central ova calcified, or, the ova having been devoured by the giant cells, only a chitinous capsule or spine remains to tell the story. In the older lesions the eosinophil cells become few or vanish from the fibrous tissue surrounding the bilharziomata, with the death of the ova which invited and maintained their presence.

BRITISH MEDICAL ASSOCIATION.

ANNUAL MEETING IN MANCHESTER.

(Continued from p. 665.)

SECTION OF PATHOLOGY AND BACTERIOLOGY.

TUMOURS OF THE INTESTINE.

WITH Prof. J. S. DUNN (Manchester) in the chair, a discussion on the Relation of Malignant Disease to Benign Tumours of the Alimentary Tract was opened by Prof. MATTHEW STEWART (Leeds). He drew attention to the frequency of the casual finding of such benign tumours post mortem, many of them of little importance per se, but a few being attended with serious complications. Such tumours he classified into (1) connective tissue, (2) epithelial. The first group consisted of lipomata and leiomyomata. The former were rare and of small size; the variety occurring in the stomach was submucous while those of the intestine were usually subserous. Leiomyomata were more common and were flat and button-like. These latter occasionally became sarcomatous, but whether the tumours were innocent at first with subsequent malignant degeneration or whether they were sarcomatous from the outset was difficult to determine. Myosarcoma was more frequent in the stomach than in the intestine.

The epithelial tumours, said Prof. Stewart, were of much greater importance. They were usually adenomatous with a tendency to become polypoid and might attain a very large size. Their polypoid form was believed to be due to the mechanical action of the gut, and the pedicle was often quite definitely not composed of tumour tissue. He suggested that the submucosal thickening which occurred in relation to these tumours was mechanical rather than inflammatory. Other simple epithelial tumours described were adenomyomata and pancreatic heterotopia. There is no evidence, said the speaker, that either of these is specially liable to malignant change. With regard to adenomatous polypi, Dukes had found such tumours in 25 out of 33 consecutive surgical cases of carcinoma of the rectum. In the case of the stomach there was also a growing tendency to associate malignant with benign tumours. Analysing 11,000 autopsies at Leeds Royal Infirmary, Prof. Stewart found 47 cases of polypi of the stomach and about a quarter of these were associated with carcinoma. The total number of cases of carcinoma of the stomach, however, in these post-mortems was 263, so that only 4·9 per cent. were associated with polypi. Although polypi must be accepted as precursors of malignant disease of the stomach in a small percentage of cases, the association was much more intimate in the large intestine.

The speaker next reviewed the criteria of early malignancy in gastro-intestinal polypi. Invasion of the muscularis mucosæ he considered the most important single phenomenon. In earlier cases where there was only irregularity and de-differentiation of cells the diagnosis was more difficult, but such cases must be regarded with grave suspicion. Carcinoid tumours occupied an intermediate position between the simple and malignant. They were locally infiltrative, but never developed the characters of frank carcinoma. A review of the experimental results of many workers revealed very little of positive value concerning the point under discussion. Ishibashi and Otani (1921) had produced papillary adenomas in the stomach of animals by means of submucous injections of tar. Leitch had obtained negative results by injection of tar per rectum. Menetrier had succeeded in producing squamous carcinoma in the stomach of a rat by administration of tar, while Schabad had obtained negative results in mice with similar experiments.

Prof. ARCHIBALD LEITCH (London) described four cases of benign tumour of the small intestine, but on account of the extreme infrequency of malignant tumours in this situation he considered the relationship between innocent and malignant tumours here was hardly worth discussing. In the case of the large intestine the number of museum specimens kept to show benign and malignant tumours occurring together tended to produce a wrong conception of the importance of benign tumours as precursors of cancer. In experimental work and in the study of cancer in various parts of the body it had been shown that simple tumour formation occurred in numerous foci with only one or a few of these becoming malignant. He would like to believe that such a condition occurred in the intestine, but observation on a large number of cases of carcinoma of the colon led him to think that such a process was quite uncommon. He doubted the importance of the extremely small papillomata so often described, and he believed that such tumours should be neglected in an observation of this kind. Lack of controls greatly reduced the value of many observations. When, however, there were definite adenomata in the intestine there was a great tendency for these to become malignant. He was unable, however, to support Dukes's theory of retrogression. In his experimental work Prof. Leitch had used tar and the products of putrefaction with negative results. His general conclusion was that the case had been overstated and that in reality benign tumours were of little importance as precursors of cancer in the large intestine, although when adenomata do occur there is a great tendency for them to become malignant.

Dr. CUTHBERT DUKES (London) described the last 75 cases of cancer of the colon that he had examined. He classified these into (*a*) those in which malignant growth had infiltrated the submucous coat but had not reached the muscle coat; (*b*) those in which the muscle coat was invaded but without spread by direct continuity into the perirectal tissues; (*c*) in which spread had occurred into the perirectal tissues. In group (*a*) was only one tumour and this was associated with papillomata. Group (*b*) consisted of 18 tumours, half of them being associated with papillomata which were only present in less than a third of the 56 cases in group (*c*). Dr. Dukes concluded that papillomata are more common in early than in late cases of cancer. The speaker suggested that the rarity of occurrence of papillomata in group (*c*) could only be explained by the supposition that some sort of immunity developed as a result of cancerous invasion, and this led to a retrogression of the epithelial proliferations in the immediate neighbourhood. The frequency of papillomata in early cancer lent support to the view that adenomatous polypi preceded cancer of the rectum. Indeed in cases of familial polyposis of the intestine this almost invariably occurs. The diagnosis of papillomata was made only when these were visible at first glance and when several were present. Cases in group (*a*) were characterised by epithelial proliferations heaped up above the surface of the surrounding mucous membrane, whereas in group (*c*) the cases had excavated ulcers with raised margins. Group (*b*) cases were intermediate between these two. These were not different types of growth but different stages in the development of malignant growth. In the early stages epithelial proliferations projected into the lumen of the bowel and the tumour had the structure of an adenoma or villous papilloma. The onset of malignancy was marked by invasion of the submucosa and this was followed later by ulceration. If the tumour was removed before there was evidence of invasion it would be classified as an adenoma, if after invasion as a carcinoma. Thus, in the precancerous or pre-invasive period the epithelial proliferations in carcinoma and adenoma were indistinguishable. It was not possible to express statistically the frequency with which cancer developed in a pre-existing papilloma compared with its origin from a flat region of the mucous membrane, but malignant degeneration of an adenomatous polyp was met with commonly, and the earliest cancers in museum collections were usually of this type. Dr. Dukes concluded that adenomata and carcinomata in the colon were often related phases in the incidence of malignant disease.

Dr. WILLIAM SUSMAN (Manchester) analysed and classified simple and malignant tumours of the alimentary canal found in 883 autopsies at Manchester Royal Infirmary. In 38 cases there were polypi of colon, associated in every case with hyperplasia of the mucous membrane. They were twice as common in males as in females and were found most frequently between the ages of 40 and 60. In some cases polypi were limited to one or other segment of the colon without there being any predominant distribution. In other cases polypi were distributed throughout the large intestine. Single polypi were present in nearly half the cases. In 17 of these 38 patients there was associated cancer; in 10 of them this was situated in the colon, 2 in the stomach, 2 in the œsophagus, and 3 elsewhere. The speaker concluded that polypi were definitely associated with malignant disease of the colon, and that the polypi underwent changes analogous to those observed in the skin of the mouse during tar treatment. Solitary polypi might and multiple polypi were very likely to be potentially malignant.

Dr. J. S. YOUNG (Leeds) pointed out that skatol and indol injected subcutaneously had been found to produce simple hyperplasia; since these substances were increased in constipation he suggested a possible relationship to tumour development. Dr. Young had also shown that bile-salts have a marked action in producing epithelial hyperplasia and this opened up another field for investigation.

Prof. STEWART summing up said that the speakers were agreed that papillomata of the colon were sinister manifestations and frequently developed into malignant tumours. There was some difference of opinion as to the relative importance of benign tumours in cancers of the intestine taken as a whole and it seemed that much depended upon the criteria of the diagnosis of polypi.

Dr. D. F. CAPPELL (Glasgow) read a paper on the

Reticulo-endothelial System as Studied by Intravitam Staining.

This system, he said, consisted of cells which were widely scattered throughout the body and possessed certain physiological properties in common. They were concerned in ingestion and storage of particulate matter and substances in solution as well as the phagocytosis of micro-organisms. They became prominent in certain pathological conditions, especially in cases of excessive blood destruction, when excess iron was stored, and in cases of perverted lipoid metabolism. The distribution of reticulo-endothelial cells might be determined by the injection into animals of various dye substances which were taken up by the cells. Particulate matter such as india ink was taken up rapidly while dyes in solution, such as trypan-blue, required to be present in the circulation for some hours before staining was intense. The distribution was described as (1) cells lining the vascular channels of the liver, spleen, bone-marrow, and lymph glands; (2) reticulum cells of the spleen, lymph glands, and bone-marrow; (3) histiocytes occurring in all connective tissue except that of the central nervous system; (4) a few mononuclear cells in the circulating blood. Vital staining might be applied to the study of cells occurring in inflammatory processes. Using a dye such as trypan-blue it was not possible in this way to distinguish histiocytes originally present in the tissues from macrophages which had entered the inflammatory focus from elsewhere, but by employing a blue vital stain before inducing an inflammatory process with a subsequent red stain when the lesion had developed it was possible to distinguish the original reticulo-endothelial cells from those which had subsequently developed the characters of phagocytes. It was possible also to recognise in an inflammatory lesion monocytes which were derived from the blood stream by previous injection of india ink, since these cells took up the black particulate matter. The method of intravitam staining could also be used, said Dr. Cappell, in the study of so-called reticulo-endothelial blockade. He believed that it was impossible to produce such a condition by injection and splenectomy, so great was the cell regeneration.

Prof. LORRAIN SMITH (Edinburgh) pointed out that Dr. Cappell had described the occurrence in inflammatory tissue of unstained macrophages even after injection of vital dye. He wished to know where these came from.—Dr. CAPPELL in reply stated that certain cells of the reticulo-endothelial system failed to stain and these he regarded as immature but potential macrophages.

Prof. J. S. DUNN asked whether Dr. Cappell could state what was the relationship between monocytes in the blood stream to the other varieties of cells described, and whether the small mononuclear could be distinguished from lymphocytes.—Dr. CAPPELL replied that the small mononuclear differed somewhat in mitochondrial structure, although he believed both types of cell to be capable of further development if they left the blood stream and entered inflammatory tissue.

SECTION OF ORTHOPÆDICS.

OPERATIVE TREATMENT IN TUBERCULOSIS OF THE LARGER JOINTS.

Mr. G. R. GIRDLESTONE (Oxford), who opened the discussion, explained that the field of debate had been restricted to the use of operations in the actual course of the treatment of tuberculosis, so as to exclude the wide field covered by operations for the late complications and for diagnosis. The latter were a necessity in certain early cases, where the diagnosis could be made in no other way; but even after an arthropsy had been made a few tubercle bacilli might cause great disturbance of a joint though hard to find in a piece of synovial membrane. Prof. Dreyer had suggested that the bacilli might at times be in a non-acid-fast condition and difficult on this account to observe. Mr. Girdlestone quoted a letter from Prof. Osgood of Harvard in which he referred to the risks of starting sinus formation by the exploration of a joint.

The aims of treatment were, he said, twofold: (1) to save the life of the patient; (2) to restore a safe and useful limb, suitable for the ordinary stresses of life. The dangers to life were from continuance of the tuberculosis, whether in the joint itself, or in deep lymphatic glands, whose involvement was apt to be forgotten, though probably of the first importance. It was from the lymphatic focus that the joint was first infected and that secondary infections occurred, and this focus was easy to heal in children by general hygienic measures, whereas it was rare to get it healed in adults. On the other hand, the joints of children healed with extreme difficulty, while radical operation quickly healed the joints of adults, but left them at the mercy of the lymphatic focus, so that they usually died from various secondary foci in the late stages of their ailment. In children the dangerous period occurred soon after the diagnosis was made in the early days of hospital treatment. There was, he went on, a fallacy in regarding quiescence of a tuberculous joint as cure, for even when the lesion gave no sign of activity with Thomas's tests, it might yet light up directly it was subjected to the ordinary wear and tear of life. Such a joint might do well enough for the well-to-do living a sheltered life, but it was useless to a working man. In the majority of cases treated for prolonged periods in an open-air hospital, it was only this quiescence that was obtained in the larger joints, more particularly the hip; the study of remote as opposed to immediate hospital results during the last few years had made this clear. Operative treatment was therefore advisable for quiescent joints which did not regain the full normal range of movement and did not keep it with unrestricted use; small degrees of movement simply invited strain and resultant flare-up.

Speaking of the operations suitable for various joints, Mr. Girdlestone remarked that the type of excision and radical operation which gave useful function in the upper limb seldom provided the stability essential for the lower limb, where arthrodesis was usually the operation of choice. For the knee he advised immediate arthodesis in adults and in children with destruction of cartilage demonstrable by X rays, or whose knees remained persistently inflamed after thorough conservative treatment; but he preferred to delay the operation in them till the age of 12 or 14 years. The hip presented a problem of its own on account of the varied strains to which it was subject and because the shape of the joint made intra-articular arthrodesis difficult to achieve. In the adult he advised combining the intra- with the extra-articular operation, as a mere graft was likely to break with strain. In a child with a strong fibrous ankylosis and upward subluxation, the extra-articular graft of Hibbs might be sufficient; but if much granulation tissue filled the joint, the graft was apt to be absorbed. He expressed approval of the method suggested by Wilson of Boston in bringing down a large osteo-periosteal flap from the ilium, which had a much better blood-supply than the femoral graft.

Mr. Girdlestone concluded by showing lantern-slides illustrating various types of operations with their results, and the healing of chronic sinuses by the method of wide, lateral drainage with suture of the skin to the periosteum.

Discussion.

Sir **WILLIAM WHEELER** (Dublin) disagreed with Mr. Girdlestone as to the cause of death which he thought depended on the size of the joint rather than on the condition of any deep lymphatic focus. Few cases of tuberculosis in the finger died, whereas the mortality from hip and sacroiliac disease was high; moreover, some of the worst cases were cured rapidly, when the joint focus was removed by amputation. Conversely, cases diagnosed as rheumatism and treated by heavy massage might quickly absorb bacilli from the joint and die of meningitis. The facilities available to the patient must, he said, be borne in mind in planning treatment; each joint presented a separate problem. He agreed that the surgeon should aim at bony ankylosis in any tuberculous joint in which the full range could not be obtained. Diagnosis was difficult and he suggested that the metaphyseal foci described by Stiles might result from a mixed pyogenic and tuberculous infection. There were fashions in treatment and he would like speakers to discuss the place of arthroplasty in late cases of tuberculosis of the knee, and of early osteotomy to ensure rest in active tuberculosis of the hip. He demonstrated such a result in his lantern-slides of X rays before and after joint operations. In reference to one of them, he pointed out the need for wide resection of bone in excising a tuberculous wrist.

Mr. **ALEXANDER MITCHELL** (Aberdeen) associated himself with previous speakers in finding diagnosis difficult; but without it no rational treatment could be planned. The type of ankylosis ordinarily obtained was unstable, but he had seen admirable results in Hibbs's cases at the White Plains Hospital, New York, following the "extra-articular fusion" operation. He did not think there was much shock associated with this operation. He referred to the successive fashions in the treatment of these cases: (1) operative (frequent excisions); (2) fixation by splinting for years; (3) movement by Rollier's system; (4) and now arthrodesis combined with open-air treatment. He would himself divide tuberculous joints into four types requiring different methods: (1) the synovial type with no X ray evidence, where arthropsy presented the only means of making a certain diagnosis; (2) the epiphyseal lesion well shown in the X ray, but scarcely involving the joint itself, likely to heal well and not requiring operation; (3) the case with pain and spasm well marked and with obvious involvement of the articular surfaces; and (4) the case with extensive bone destruction. The two latter types required resection or arthrodesis. In elderly persons the joint should simply be amputated.

Miss **M. FORRESTER-BROWN** (Bath) referred to the technical difficulty, in extra-articular arthrodesis of the hip, of turning the graft upside down, as advised by Hibbs; she had found it better merely to slide the graft upward and fix it in a bed, prepared by thoroughly rawing the neck of the femur, by means of catgut sutures through the muscles over it. This safeguarded the blood-supply. She also referred to the difficulty of knowing at what stage a patient with a quiescent joint would tolerate operative interference.

Mr. **H. A. T. FAIRBANK** (London) advised radical removal of the disease from the adult knee, using a tourniquet which he thought reduced the risks of generalising the infection. He had found the sulphur method of value for some of the secondarily infected joints. He did not believe in grafting for sacroiliac disease.

Mr. **WHITCHURCH HOWELL** (London) related some very late results of treatment which he had met with—e.g., a case with 9 inches of shortening of the lower limb after excision of the knee in childhood; and a woman who had survived to the age of 75 years in spite of a sinus discharging since the age of 5 years.

Mr. **A. W. ADAMS** (Bristol) asked for figures of the frequency of generalised dissemination after operations on tuberculous joints, and also whether arthritis should not be anticipated by removal of epiphyseal foci.

Mr. **W. ROWLEY BRISTOW** (London) said that examination of the synovial fluid seldom gave positive evidence in tuberculous cases, even when, as was his practice, three guinea-pigs were injected; hence a negative result was of no value. He did not consider removal of a piece of synovial membrane for diagnostic purposes dangerous. Like other speakers, he had been much impressed with Hibbs's results by fusion operations, including that on the knee, where no radical removal was attempted. He did not fear shortening from operations on the knee in childhood, as the epiphyseal line need not be reached; prolonged and careful after-treatment was necessary to prevent bending during growth. If this precaution was observed no precise age limit need be fixed. He deprecated any attempt to divide the profession into two schools of treatment, operative and non-operative; each case should be dealt with on its own merits.

Mr. **D. MACRAE AITKEN** (London) hoped that the treatment of the future would be by anticipation and prevention of tuberculosis. He agreed that the essential principle of rest for an inflamed joint could be carried out, not only by splints, but also by such operations as extra-articular fusion of the hip, osteotomy, and amputation.

Sir ROBERT JONES (who presided) also begged that there should be no attempt to form two camps with opposing methods of treatment. While he had awful memories of the old surgical epoch in the treatment of tuberculosis, he was prepared to recognise that such an operation as extra-articular arthrodesis of the hip, by providing effective rest for the joint, complied with the principles he advocated—namely, adequate fixation of the affected joint, prevention of recurrent deformity, fresh air, and general treatment. He found it hard to follow the American statistics, quoted by Mr. Girdlestone, in which only 2 out of 150 cases were completely satisfactory after three or more years of conservative treatment. Such figures would have seemed ludicrous to Hugh Owen Thomas working under conditions much less favourable.

Mr. GIRDLESTONE, in reply, said that he did not fear dissemination after operations on tuberculous joints, because the body was accustomed by then to deal with recurrent doses from the lymphatic focus. He regarded the use of a tourniquet as a safeguard and agreed that osteotomy might produce healing, although he preferred arthrodesis. He did not advise arthroplasty for tuberculous cases.

Demonstration at Grangethorpe Hospital.

At an afternoon demonstration Mr. R. OLLERENSHAW (Manchester) showed a series of cases, illustrated by simple diagrams of technique; among them, three cases of foot-drop treated by Campbell's posterior block method, some excellent results after various hip operations, and a series of congenital deformities with problems successfully overcome. A case of congenital dislocation of the hip, diagnosed as two months old, had been reduced (after Putti) without manipulation by persistent abduction of the lower limbs. Some spastic cases on whom Royle's operation of sympathectomy had been done some years previously showed only temporary improvement; better results had been obtained by Stöffel's peripheral nerve division. In a case in which synostosis of the radius and ulna had followed a forearm fracture in a child rotation of the forearm had been restored, after union of the fractures in good position, by Baldwin's method of resecting a small piece of the ulna near the wrist, so that the radius carried the ulna styloid process with it when it rotated.

Dr. H. POSTON (Manchester) exhibited results of compound fractures involving joints on which primary excision of the wound had been done within a few hours of the accident, followed by swabbing and skin infiltration with 1 per cent. mercurochrome and fixation in plaster-of-Paris. The only drainage had been down to the sutured capsule for the first 48 hours.

Dr. MARGARET GREG demonstrated a series of cases of renal rickets with dwarfing and of adolescent rickets with somewhat similar bone changes, as seen in skiagrams.

Dr. J. G. JOHNSTONE showed cases illustrating various difficulties met with in the treatment of congenital dislocation of the hip, including the development of osteochondritic changes in the head of the femur and recurrent subluxation. One case was walking well after reduction at 0 years old.

Mr. HARRY PLATT (Manchester) demonstrated transplants of the trapezius for deltoid paralysis, in which there was good stabilisation of the joint during abduction. A case of vertebral osteochondritis shown has been used by Calvé to illustrate his recent article. In two cases the power of opposition had been restored to the thumb by transplantation of the sublimis tendon of the ring-finger into the flexor longus pollicis.

Dr. S. POPE (Manchester) summarised a thesis on the experimental production of birth palsies. By using 24 dead fœtuses and extracting them from a machine by methods imitating those of obstetrics, with varying conditions of resistance, he had succeeded in producing a number of lesions of the brachial plexus and tears of the sternomastoid which correspond to those met with clinically.

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

THE following are some 1928 statistics of four large towns, with widely differing industries:—

Name of district and estimated (R.-G.) population.	Birth-rate.	Death-rates per 1000 of the population.					Death-rates per 1000 births.		
		All causes.	Tuberculosis.	Cancer.	Respiratory diseases with influenza.	Heart disease.	Infant and neonatal mortality.	Young child (1–5 yr.) mortality.	Maternal mortality, from childbirth, &c.
Sheffield .. (515,400)	16·4	11·8	0·94	1·37	1·0	1·0	73/38	41	6·0
Leicester .. (340,000)	16·2	11·9	1·24	1·42	1·5	1·8	71/31	16	3·5
Nottingham . (266,600)	17·7	12·8	1·10	1·44	2·8	1·5	85/40	28	5·5
Blackburn .. (125,100)	13·8	12·2	0·82	1·30	2·5	2·7	80/38	28	6·3

Sheffield.

Dr. F. E. Wynne draws attention to the altering age-constitution of the population and to the possibility of a progressive rise in the death-rate from all causes in the coming years. He gives a table comparing the age-constitution of the population of Sheffield at the censuses of 1911 and 1921, which shows that in the latter year there was a decrease in the population at 0–10 years, an increase at 10–20, a decrease at 20–40, and an increase at 40–80. Environmental sanitation has been improved by the completion, during 1928, of the scheme for the conversion of privies into water-closets and attention is now being turned to the substitution of modern water-closets for trough closets and waste water-closets, and of sanitary bins for the old insanitary ash-pits.

There were 61 notifications of small-pox with no deaths. The notifications of pneumonia numbered 2603, of which 328 were removed to the city hospital for treatment. The death-rate from pulmonary tuberculosis among the grinders may have been reduced by unemployment in their trade, but, however that may be, it is very satisfactory that the Sheffield death-rate from all forms of tuberculosis is the lowest of the 18 great towns of England and Wales with populations exceeding 200,000 with the exception of Plymouth (0·90) and that the Sheffield rate for pulmonary tuberculosis (0·745) is lowest of all these towns with the exception of Portsmouth (0·744). Dr. John Rennie, tuberculosis medical officer, emphasises the fact that their efforts are directed towards a decrease in the proportion of infectious cases among the notifications and the establishment of a diagnosis of tuberculosis in the earliest stage of the disease. The cases on the register at the end of 1928 numbered 5007, of which 1134, including nine children under 15 years, were "open" cases. Ninety-three per cent. of the pulmonary cases notified were examined by the dispensary staff. The number of notifications of tuberculosis of the lung was about five times the number of deaths, and the deaths were about the same in number as the notifications of "open" cases. The medical practitioners sent 2509 "suspect" cases to the dispensary for diagnosis, and in addition 2371 contacts were examined. The diagnosis of "suspects" and "contacts" often entails observation for long periods and residence in the observation beds. Thus only 124 of the suspects and 1575 of the contacts were definitely classed, without a period of observation, as non-tuberculous. The beds allotted for the treatment of tuberculosis appear to have now reached a maximum figure and waiting-lists for institutional treatment are things of the past. For respiratory tuberculosis alone there are 504 beds.

Dr. C. Lee Pattison, surgical tuberculosis officer, reports that the period of stay in the King Edward VII. Hospital for non-pulmonary tuberculosis has been reduced to an average of 275 days by securing the patients at an earlier stage of the disease. Provision has now been made for adult patients with bone or joint tuberculosis at Nether Edge Hospital. As regards light treatment, which has been continued both at the King Edward Hospital and the dispensary, Dr. Pattison says: "In some types and with certain degrees of activity of the disease, ultra-violet light treatment is indicated and proves definitely beneficial, but in other instances it should be avoided as in them it appears to be useless or even harmful. At the hospital irradiated foods have been found beneficial in some cases and may prove useful when cod-liver oil is not well tolerated. During the year a clinic for lupus has been started and up to the present the results obtained from general radiations with ultra-violet light and local treatment with a Kromayer lamp have been very gratifying.

It is still impracticable to apply all the powers contained in the Housing Acts, and there is much overcrowding. Progress has been made with reconstruction schemes. Thus in the case of three schemes, involving 173 houses, all the areas have been cleared, and the tenants moved to the Wybourn Estate, and in another area, involving 126 houses, condemned in 1928, a considerable portion has been cleared. Proceedings are pending with regard to two other areas involving 95 and 174 houses respectively. During 1928 an interesting departure was made by the allocation of 26 municipal houses to families living under unsatisfactory conditions, among whom there was an "open" case of tuberculosis. Twenty-three families have been rehoused under this scheme and their members have been examined at the dispensary, and a striking improvement in the health of the children has been noted since rehousing.

A table given by Dr. Wynne shows that the maternal mortality from childbirth has been considerably higher during recent years. Thus in 1923 it was 4·02, and in the five succeeding years 4·53, 4·93, 5·99, 7·27, and 6·04. The puerperal sepsis rate alone during the last three years was 2·33, 3·64, and 3·79.

Leicester.

Dr. C. Killick Millard gives a survey of the small-pox experience in his city which for 40 years has "set the compulsory vaccination law at defiance." During that period 90 per cent. of the children born in Leicester have not been vaccinated. Up till last year there were four small epidemics—namely, in 1892–93 with 358 cases and 21 deaths; in 1902–03 with 394 cases and 21 deaths; in 1903–04 with 321 cases and 4 deaths; and in 1925 with 72 cases and no deaths. The last mentioned was of the mild type which apparently breeds true and Dr. Millard goes on to describe the epidemic of 1928–29 which was also of the mild type. On May 11th, 1928, small-pox was introduced by a tramp and from that date there were other introductions of the disease, generally by missed cases, causing spread of the infection with intermissions up to June, 1929. In all there were 90 cases in 1928 and 107 in 1929. There were no deaths. The vaccinated cases numbered 23 and the unvaccinated 174. Medical practitioners were encouraged to visit the small-pox hospital to familiarise themselves with the signs and symptoms of the "mild" disease. Some who had not been recently vaccinated refused—unwisely, says Dr. Millard, as every doctor may have to attend a small-pox case and should surely protect himself by vaccination. Vaccination was pressed in the case of "house" contacts, but not so much so in the case of "outside" contacts. Of 542 house contacts, 303 submitted to vaccination, whilst of 237 outside contacts 103 were vaccinated. A great point is made in Leicester of close supervision of contacts. Exclusion of contacts from work rested with the employer and the amount paid in compensation to contacts kept from their work was £153. The number of new cases occurring was included in the weekly returns sent to the press, but there was no attempt to induce the public to get vaccinated. Apart from the contacts the vaccination figures were lower than usual. Dr. Millard throws out the suggestion that when the administration of the Vaccination Act is handed over to the health authorities, it might be made the subject of local option. He states that there has never been a case of encephalitis following vaccination in Leicester, but points out that such an occurrence would be rather unlikely when there is so little vaccination.

The year 1928 was epidemic for scarlet fever. There were 1071 cases with four deaths, and Dr. Millard points out that the "new treatment" was very successful in cutting short the disease and preventing complications. Dr. H. Stanley Banks, the medical superintendent of the hospital, described this treatment by the intravenous injection of antitoxin in a paper in THE LANCET of Feb. 23rd, 1929. The cases treated in hospital were divided into two groups. Group I. included all the more severe cases numbering 404. They were all treated intravenously, had a complication rate of 3·2 per cent., with one death, and their average stay in hospital was 17·7 days. Group II. included 458 cases who had no antitoxin and 102 who had it intramuscularly. This group included all the milder cases. They had a complication rate of 23·7 per cent. and their stay in hospital averaged 26·8 days, and there was also one death among them. Dr. Banks is most enthusiastic about the treatment and considers the whole outlook in the hospital treatment of scarlet fever has been altered thereby. Scarlet fever wards under the new treatment may be almost surgically clean. There are practically no complications and scarcely any medical or nursing treatment is needed after the first few hours. Hospital beds go twice or thrice as far.

Dr. Banks has also made a trial of the sanocrysin treatment of pulmonary tuberculosis in 22 cases. He thinks the type which did best was the middle case, neither early nor too advanced, which did not appear to respond well to routine sanatorium treatment. Fourteen of this type were treated; in six the results were remarkably good, and in eight they appeared to be favourable. He points out that there has been no opportunity to speak of any but immediate results and that the late results will probably depend on the patient's ability to conform to the rules of the tuberculous life. The cost of sanocrysin for the first course is about £3, and for the second course £2 6s. 8*d.* per case, and the considerable labour involved in giving the injections, making tests and examinations, and keeping records makes the treatment expensive. The Leicester special clinic for the early diagnosis of cancer which was started in July, 1927, and restricted to women and affections of the breast and uterus, has now been extended to all forms of cancer in either sex.

Municipal houses, Dr. Millard points out, have done little or nothing to benefit the class most in need of relief, and he commends the solution of the problem put forward by the Housing and Town Planning Council of Great Britain in their report entitled "A Policy for the Slums." This report advocates a children's rent allowance scheme. Dr. Millard also emphasises the fact that the municipality can safely build a larger proportion of houses with two bedrooms, seeing that as landlord it has the power to control their use.

Blackburn.

Dr. V. T. Thierens, in his first annual report, says the year has been one of great industrial depression, with consequent unemployment. The death-rates from respiratory diseases and from pulmonary tuberculosis among the cotton operatives were lower than in 1927. During the year 94 municipal and 41 private enterprise houses were built, and at the end of the year 60 municipal and 70 private enterprise houses (none of which was State-aided) were under construction. The housing problem in Blackburn is less urgent than in other towns. The population is actually less than it was in 1910 to 1924. There are no real slums, although there are some areas of unsatisfactory property. There were, however, 471 Blackburn residents living in rooms, who were on the waiting-list for municipal houses at the end of 1928. There are 88 houses let in lodgings, housing about 1000 persons, with poor accommodation and excessive rents. In some instances the rent for two partly furnished rooms exceeds that asked for houses on the corporation estates. At the end of the year there were 57 caravans in use as human habitations. There are 181 factory chimneys, 103 of which have smoke-preventing appliances. Blackburn's effort to prevent industrial smoke does not appear to be energetic. The permissible limit of black smoke for a furnace serving one boiler is 4 minutes in the hour, or twice that of Sheffield. The limits for 2, 3, and 4 boilers are 5, 6, and 7 minutes respectively. During the year 103 observations were taken and in 54 excessive smoke was emitted. The only action mentioned is the service of 21 informal and two statutory notices.

The veterinary inspector, Mr. E. J. Burndred, reports that as the result of regular inspection of the cattle aided by examination of milk samples, three cows in the borough farms were found with tuberculosis of the udder, and seven cows were slaughtered and one died which suffered from advanced tuberculosis. The number of milk cows stalled in the borough is not mentioned. There are three farms supplying Certified milk to Blackburn, two local and one some distance away. The price of this milk ranges from 7½*d.* to 4*d.* per pint. There are 18 farms in the district producing Grade A milk, five of which are in the borough and 13 in the county. The price is from 3½*d.* to 4*d.* per pint. Two dairies, one in the borough, are licensed for pasteurised milk, and a new dairy is being established in the neighbourhood by a number of coöperative societies for the pasteurisation and bottling of milk, so that in the near future a much larger proportion of Blackburn's milk will be pasteurised. During the year 446 samples of milk were examined for the presence of dirt. The samples taken from producer-retailers in the borough were better as regards contamination than those taken from producer-retailers outside the borough and those taken from retailers in the borough, who procured their supplies from outside, were much worse than the two classes first mentioned. A standard has been laid down for the equipment to be required from milk retailers in the borough. A specimen plan is given in the report, showing the arrangement of the two rooms needs for washing and storing the utensils and for storing the milk respectively. At the end of the year about 12 of the 50 retailers had complied with these suggestions. The seventh clean milk competition extended over the whole year. The competitors are divided into two classes, one for Certified and Grade A milk, and the other for all other milk. There were 13 entries for the one class and six for the other, but the ordinary milk producers do not yet take much interest in the competition.

There were 104 notifications of diphtheria with a case fatality of 10·49 per cent. Twelve of the 18 fatal cases received no antitoxin treatment for 4 to 12 days after the onset of the disease. There were ten notifications of small-pox, all of the mild type. A table is given showing the condition at the end of 1928 of the patients discharged after treatment for pulmonary tuberculosis from Meathop Sanatorium. Of 20 patients discharged in 1909 or before, 12 are dead, 7 untraceable, and 1 is in full work with no symptoms. Of 30 discharged in 1916, 15 are dead, 5 untraceable, and 9 in full work and 1 unable to work. Of 24 discharged in 1923, 8 are dead, 4 untraceable, 3 at full work with no symptoms, 4 in partial work, and 5 alive. Of 17 notified cases of ophthalmia neonatorum one became totally blind and two were left with serious and disabling impairment of vision. In five of the cases domiciliary nursing was undertaken by the Nursing Association under agreement with the corporation. A bed is now available at the corporation hospital for in-patient treatment.

Nottingham.

Dr. Philip Boobbyer informs us that in 1916, 20 months after the outbreak of war, the city council discontinued printing annual health reports and gave instructions for the statistical and other records to be prepared in manuscript. The document just issued is therefore a survey of the 13 years for which printed annual reports are lacking. It is also Dr. Boobbyer's farewell report after 40 years' service as medical officer of health of Nottingham, and is commented on elsewhere in this issue.

MENTAL HOSPITAL REPORTS.

OF the two *Kent County Mental Hospitals*, that at *Barming Heath, Maidstone*, had 1925 patients in residence on Dec. 31st, 1928. This was an increase of 72 on the previous year, despite the transfer of 40 men. The medical superintendent hopes that the shortage of accommodation will be met by the provision of an admission block. The admission-rate for women was a record for the hospital. The recovery-rate was 24·7 per cent. and the death-rate 7·1 per cent. Autopsies were held in 80 out of 87 cases. Eighteen patients are under treatment for tuberculosis, but the death-rate from this cause was half that of the average in mental hospitals. There was one case of dysentery, the first for three years, two cases of erysipelas, eight cases of scarlet fever, and some influenza. The occupation therapy department had a very successful year; the printing and bookbinding department supplied bound periodicals for the wards. Parole is given freely. A kinematograph apparatus has been fixed in the recreation hall. Forty-one attendants and 49 nurses are certificated or registered, and 18 women nurse in the male wards. Twelve nurses arrived from Denmark last year for a six months' course of training in this hospital. At *Chartham Downs, Canterbury*, there were 1854 patients at the end of last year, 40 cases having been transferred from Barming Heath. Here also the medical superintendent hopes for a new block for recent and curable cases. The recovery-rate was 28 per cent. and the death-rate 8 per cent. Post-mortem examinations were held on 90 of the 127 patients who died, and the pathological department carried out over 2000 routine examinations. The hospital was entirely free from both influenza and dysentery, but the death-rate from tuberculosis is rather higher than the average. A verandah was added to the female tuberculosis ward, and plans for a new operating theatre have been passed. More accommodation is needed for the nursing staff, and plans are under consideration. Thirty-eight attendants and 23 nurses are certificated or registered; no women nurses are employed on the male side.

Barnwood House Hospital for Mental and Nervous Disorders, Gloucester, records a successful year of work in 1928. On Dec. 31st there were 152 patients, including 10 voluntary boarders. There was a recovery-rate of 35 per cent. and a death-rate of 8 per cent. The general health was good. Three of the five new bedrooms were provided with "Vita-glass" verandahs. The city having extended an electric cable past the hospital, the committee at once made arrangements for securing a supply of current. The 33 acres of land purchased in 1926 have now been taken over as additional farm land. Eight patients of each sex were allowed out of the grounds, and a seaside house for the summer was taken at Tenby. Members of the staff have held classes in rug-making and other handicrafts. A physician, a surgeon, a pathologist, and a dentist attend when required. Of the attendants 63 per cent. and of the nurses 41 per cent. are certificated, seven having obtained their R.M.P.A. certificate during the last year.

At the *City of Birmingham Mental Hospital* there were 2071 patients on the books on March 31st, 1929. Lack of accommodation is being met by the inclusion of an adjoining fever hospital and private house, the former for female patients and staff, and the latter for male convalescents. As usual, research has played an important part in the year's work, and the chief medical officer submits a preliminary report from the three institutions together. The dental surgeon notes that, as in former years, not more than 2 per cent. of the patients admitted can be said to have a healthy dentition. More conservative dentistry is found in the younger patients, and this is held partly responsible for the greater amount of focal sepsis. Septic conditions of the upper air passages were found in half the cases admitted, the commonest condition being a multi-sinusitis. The tonsils were diseased in 52 per cent. of the cases investigated, and adenoid vegetations were removed from 10 per cent., all adults. The ear, nose and throat surgeon performed 230 operations during the year, and, together with the director of the research laboratory and chief medical officer, has published a report on the relation of sinusitis to mental disorder. Another communication submits that disease extending from the sphenoidal sinus may cause symptoms indicating disorder of the pituitary gland. Gynæcological disturbances were found in 67 per cent. of the women admitted, but the septic condition was only serious in one case. Most of the women suffered from chronic infections of the cervix. A number of displacements and other gynæcological conditions were corrected. Further evidence was collected during the year to associate mental disorder with influenza. A striking absence of noise and excitement in the wards is attributed to the early and systematic treatment of septic conditions. In Birmingham they have no doubt that ultra-violet rays have value when suitably applied to mental disorder.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED SEPT. 21ST, 1929.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 119 (last week 96); scarlet fever, 2322; diphtheria, 1237; enteric fever, 116; pneumonia, 624; puerperal fever, 31; puerperal pyrexia, 91; cerebro-spinal fever, 13; acute poliomyelitis, 18; acute polio-encephalitis, 3; encephalitis lethargica, 26; continued fever, 2; dysentery, 30; ophthalmia neonatorum, 108. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on Sept. 24th–25th was as follows:—Small-pox 122 under treatment, 19 under observation (last week 121 and 15 respectively); scarlet fever, 1533; diphtheria, 1645; enteric fever, 18; measles, 204; whooping-cough, 203; puerperal fever, 27 (plus 7 babies); encephalitis lethargica, 125; poliomyelitis, 4; "other diseases," 13. At St. Margaret's Hospital there were 24 babies (plus 10 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 2 (1) from enteric fever, 15 (5) from measles, 8 (2) from scarlet fever, 24 (2) from whooping-cough, 27 (2) from diphtheria, 144 (27) from diarrhœa and enteritis under two years, and 17 (3) from influenza. The figures in parentheses are those for London itself.

Of the deaths from diarrhœa (which have again increased by one-third) 12 each were reported from Birmingham and Liverpool, 6 from Sunderland, 5 from Hull, 4 each from Walsall and Middlesbrough, while Glasgow, Dublin, and Belfast reported 5, 8, and 9 respectively. Two deaths from measles occurred in Manchester. Three from scarlet fever and 4 from whooping-cough in Liverpool. The death from enteric fever was reported from Leeds.

The number of stillbirths notified during the week was 238 (corresponding to a rate of 38 per 1000 births), including 49 in London.

Reviews and Notices of Books.

OSTEOMYELITIS AND COMPOUND FRACTURES AND OTHER INFECTED WOUNDS.

Treatment by the Method of Drainage and Rest. By H. WINNETT ORR, M.D., F.A.C.S., Chief Surgeon of the Nebraska Orthopedic Hospital. London: Henry Kimpton. 1929. Pp. 208. 21*s.*

IN this book Dr. Orr describes his original method for the treatment of osteomyelitis and compound fractures. In cases of osteomyelitis the infected bone is incised early with adequate opening into the medulla, and the cavity is packed with vaseline gauze. The limb is immobilised in correct alignment by plaster casts or adequate splints. Dressings are done at infrequent intervals and only in consequence of rise of temperature, odour, or other special reasons. In compound fractures the principle involved is the maintenance of correct length and alignment by extension, whether by adhesive moleskin straps or by ice tongs or pins, incorporated into a plaster cast. Fixed extension having been achieved, the wound is treated by adequate drainage, and vaseline packs with very infrequent dressing. Dr. Orr's book contains much special pleading, but his thesis has both reason and results behind it, and its adoption would do much to improve the treatment of infected bone lesions. Chapters on antiseptics and on the lessons of the war illustrate the way in which Dr. Orr has reached his present views, and case-histories of patients treated by this method by the author and by other surgeons make convincing reading.

That Dr. Orr's general principle is right we have no doubt at all, and in establishing it he has achieved a notable surgical advance. Whether the details of his technique are all equally commendable is not so certain, but is of less moment. In osteomyelitis cases particularly the thoroughness of the primary operation must be of paramount importance, and the author appears to us to underrate his surgical skill in his anxiety to give full credit to the principle of his method. On the whole, however, he has put his case fairly, and his book should be read by every surgeon. Dr. John Ridlon contributes a delightful introduction. We doubt whether the general surgeon is quite so black as Dr. Ridlon paints him, but feel sure he will enjoy such witty castigation. Dr. Ridlon quotes Talleyrand's saying, "Be zealous; but don't be too damned zealous"; that remark could be applied to his own defence of the orthopædist as well as to the alleged officiousness of the general surgeon.

SLEEP.

The Treatment of Its Disorders. By R. D. GILLESPIE, M.D., M.R.C.P., D.P.M., Physician and Lecturer in Psychological Medicine, Guy's Hospital. London: Baillière, Tindall and Cox. 1929. Pp. 276. 7*s.* 6*d.*

THIS addition to the Minor Monograph Series is intended to indicate to the practitioner the various means by which insomnia may be treated, together with a rational basis for the methods of treatment recommended. Since no comprehensive monograph on the subject of sleep and its disorders has appeared in English for some years the book supplies a definite demand, and it gives an entirely up-to-date presentation of the subject. The first section considers the several physiological mechanisms such as variations in the depth of sleep and the state of the reflexes, circulatory, respiratory, and excretory systems during sleep. Recent work shows that the basal metabolic rate is 15 per cent. less during sleep than in the waking state, and the investigations of A. Waller, Farmer, Richter, and others indicate that the electrical resistance of the body is a measure of the depth of sleep since the resistance rises during sleep and falls towards the onset of the waking state. The effects of sleeplessness both in man and animals are next discussed. It is comforting to read the result of a review of the available experimental evidence; the conclusion is reached that by no known method has it been possible so far to demonstrate any but trifling physical or mental changes after prolonged insomnia in man. At present all that can be said is that the signs are entirely subjective and that they can be abolished after as many as 115 hours of insomnia by a single and not unduly prolonged period of sleep. It has often been maintained that sleeplessness may lead to mental disorder, but it is true that the examples usually cited are those of anxiety states, schizophrenic, or one of the common "functional" syndromes. If insomnia were the direct cause of mental disturbance it would presumably act by virtue of definite nerve-cell changes, and the resulting mental disorder would be of the "organic" type such as delirium, impairment of memory, and so forth. Such states, it is considered, are the only relevant types of reaction to insomnia and are rare. Most people will agree that anxiety and worry regarding insomnia are more potent in aggravating an anxiety state than the actual loss of sleep, and that sleeplessness in mental disorder is more symptomatic than causative.

Dr. Gillespie divides the various types of sleep disorder into three main classes: 1. Qualitative alterations, such as decrease (insomnia) and increase (somnolence). 2. Alterations in the incidence of sleep—e.g., attacks of sleep (narcolepsy), and the reversal of sleep rhythm, such as occurs in encephalitis lethargica. 3. Abnormal interruption of sleep—hypnagogic hallucinations, tendon-motor shocks, nightmares, night terrors, somnambulism, &c. From the therapeutic standpoint the types of insomnia are classified as follows: 1. Sleeplessness due to physical disease—(*a*) of the central nervous system, (*b*) of other parts of the body. 2. Sleeplessness due to external irritation—e.g., climatic conditions. 3. Sleeplessness resulting from mental causes. This classification appears unnecessarily complex, and the simpler method adopted by other authors which divides the causes of insomnia into two main groups—(1) physical and (2) psychical—would include all the above. The difficult subject of treatment is admirably dealt with in this book and the various hypnotics in use are discussed. The author has been lucky in finding that "paraldehyde in doses of two to three drachms is often effective" in cases of sudden excitement and delirium tremens. The exceptional instances mentioned—in which the dose has to be repeated in an hour or so—in our experience are more often the rule. The judicious use of the barbitone series of hypnotics is rightly defended. Finally, the various theories as to the nature of sleep are reviewed in an interesting manner, and especially that relating to the possible presence of a sleep-controlling centre in the region of the third ventricle and Pavlov's view which identifies sleep with widespread cortical inhibition.

The book may be read with pleasure and profit by students and practitioners.

OTOSCLEROSIS.

A Résumé of the Literature to July, 1928. Compiled under the direction of the Committee on Otosclerosis, American Otological Society. New York: Paul B. Hoeber. 1929. Two vols. Pp. 724. $15.00.

THIS work, which is claimed to be the first comprehensive survey of the literature on this subject ever made, is a résumé of all the literature on otosclerosis down to July, 1928. The compilation has been carried on under the supervision of Dr. Arthur B. Duel as part of a programme of research in this disease begun by the American Otological Society under a grant of $90,000 made by the Carnegie Corporation. The Committee have begun their work in the right way, for it is essential that a research of this nature should start with a full record of past investigations. The work is well edited and arranged, and is supplied with a full index of subjects and another of personal names, repeated in each volume, while the second volume also contains a complete bibliography arranged alphabetically under the names of authors. The first volume deals with the pathology and ætiology of otosclerosis, and the second with symptoms, diagnosis, and treatment. Treatment is discussed under the heads of local surgical measures, local non-operative measures, and general treatment, and, being largely historical, is partly concerned with methods which have been tried and abandoned. It forms somewhat melancholy reading, for it tells a story of therapeutic efforts ranging from removal of the stapes to the use of radium and X rays, some of which have been launched with enthusiasm only to be relinquished on further trial. Further research is urgently needed, for there is at present no reliable method of treating this widespread and serious affection.

The work is a compilation to which the editors have refrained from adding comments of their own. As a work of reference it should be in the hands of every otologist.

MEDICINE: ITS CONTRIBUTION TO CIVILISATION.

By E. B. VEDDER. London: Baillière, Tindall and Cox. 1929. Pp. 398. 22*s*. 6*d*.

Colonel Vedder has put together an excellent account, for popular and semi-popular consumption, of the causes of disease and of what has been achieved in disease prevention and what is to be aimed at and hoped for in the future. The first part gives a sane and sensible discussion of diet, exercise, ventilation, &c., and adequately describes the important features of infectious diseases. The second part summarises the facts of the decline in the death-rate and analyses the components of the increase in the average expectation of life which is the triumph of modern sanitation. He draws the sound conclusion—if combined and sincere effort can do so much, it can doubtless do much more, and at a small cost. The queer thing about the book is its title; the contribution of medicine to material well-being is obvious enough, but has it done nothing for the mind and spirit as well?

AN INTRODUCTION TO THE HISTORY OF MEDICINE.

With Medical Chronology, Suggestions for Study and Bibliographic Data. Fourth edition. By FIELDING H. GARRISON, A.B., M.D., Lieut.-Colonel, Medical Corps, U.S. Army, Surgeon-General's Office, Washington, D.C. London: W. B. Saunders Company, Ltd. 1929. Pp. 996. 55*s*.

Garrison's "History of Medicine" needs no introduction to English readers. It is seven years since the appearance of the last edition, and while there may not be very much to add to the earlier sections on the history of medicine, many developments which occurred during the decade following the war had to find a place. It is in the later chapters, therefore, that the reader must look for changes; the chronological *section* has been increased *nearly twofold*. A new chapter on medicine in prehistoric times has been added and forms the second chapter of the present edition. In dealing with the history of recent advances the author has wisely confined himself to giving salient examples, realising that to attempt exhaustive handling would be premature and confusing to the reader. In view of the amazing complexity of the subject praise is due to Colonel Garrison for the way in which he has dealt with his material; nothing of importance seems to have been omitted, and the student will find in this volume an excellent epitome of medical history. Anyone interested either in the works of the fathers of medicine, or in the men themselves, or in the history of epidemics or diseases will find information in this book, and if it is not full enough for his purpose he can refer to original sources to which references are given. In order to keep the size of the book within reasonable bounds it has been necessary to print some of the sections in smaller type, but the printing and paper are so good that no strain is thrown on the eyesight of the reader.

Laboratory Manual for Comparative Anatomy.

By Malcolm E. Little and Rudolf T. Kempton, New York University. New York: The Macmillan Company. Pp. 286. 10*s.*

This book is written as a practical guide for students in American laboratories, a fact which renders it in some ways less apt for English students. Alligators, for example, are not common objects in laboratories over here, nor do we often see Necturus or Cryptobranchus given out, as one may distribute frogs, to waiting classes. But these details need not be considered seriously. The book, wherever we have tested it, gives accurate information, and the directions are likely to be of practical value in laboratories where the help of a demonstrator is available if required. When one realises that the book is intended as a compromise between systemic and systematic teaching, and is divided into distinct parts allowing change of order, one's first sense of slight confusion in arrangement is dispersed. The usefulness of a laboratory manual depends largely on the text-book employed at the same time. This book seems to us to provide a good course for students if used in conjunction with a suitable larger book.

The Visceral Nervous System.

En oversikt over den kliniske undersökelse av det viscerale nervesystem og en kritikk av de forskjellige prövers praktiske verdi stöttet paa egne undersökelser. By Dr. G. Langfeldt. Bergen: J. W. Eide's Boktrykkeri. 1929. Pp. 134.

This monograph includes a review of the clinical examination of the visceral nervous system and a criticism of the practical value of various tests of its functions. Dr. Langfeldt has been awarded Prof. Skjelderup's gold medal for the work here published, which is based on studies undertaken in Hamburg and Bergen, the experiments being carried out at the Friedrichsberg Hospital in Hamburg and the Haukeland and Neevengaard Hospitals in Bergen. In his introduction the author produces physiological and anatomical evidence which shows that there is no absolute functional antagonism between the sympathetic and parasympathetic systems. Much space is devoted to tests with atropine and pilocarpine, as well as to physical tests, such as Aschner's reflex. Many of the conclusions to which the author comes are negative, and he has found that the subcutaneous tests with various drugs (pilocarpine, &c.) are worthless in the diagnosis of chronic encephalitis, dementia præcox (of which alone he examined 71 cases), and various other mental diseases. Summaries in German and English are appended, but there is no bibliography—a rather unconventional omission.

Bacteriology and Sanitary Science,

By Louis Gershenfeld, Ph.M., B.Sc., P.D., Professor of Bacteriology and Hygiene in the Philadelphia College of Pharmacy and Science, Philadelphia. Philadelphia: Lea and Febiger. 1929. Pp. 432. $4.00.

This is a relatively short text-book on bacteriology. The subject is treated mainly from the general hygienic and epidemiological points of view, and in consequence the descriptions of individual species and of their pathogenic effects are reduced to a minimum. The book is primarily written for students in pharmacy, chemistry, and allied sciences, but it is nevertheless dominated by the pathogenic micro-organisms, both human and animal, and only brief reference is made to the field of industrial bacteriology. On the whole a very fair account of these aspects of the science is presented, without many details of technical procedures. The Wassermann and Widal tests are described in general terms, from which the reader will gather their import and their application, but without necessarily realising that "complement" is in practice usually synonymous with guinea-pig's serum. This example is intended not to criticise but to explain the scope of the book. The allocation of 40 pages to the technique of culture and staining do not accord with the disregard for technical detail which pertains elsewhere. A similar lack of balance is observable in other places. Thus the virus diseases are allotted only ten pages and suffer badly from this compression, whilst diseases of plants are hardly worth mentioning if less than a page can be spared to them. It does not help the reader to be told that "the following three methods are employed in making microscopic examinations of milk: Prescott-Breed method, Stewart-Slack method, and the Doane-Buckley method" if the significance of this imposing concatenation of proper names is not explained to him. The arrangement of the book is curious. Why should the bacteria be separated from the higher bacteria by an article on sterilisation, and that article separated from the allied subject of insect extermination and insecticides by chapters upon animal parasites and venomous reptiles? The chapters on sterilisation and disinfection are amongst the most comprehensive in the book. Apart from these minor matters of detail the book is well adapted to give the students for whom it is designed a sound conception of bacteriological principles and to the practising pharmacist a clear conception of the nature and rationale of many of the products he is now called upon to sell.

Handbook of Bacteriology.

Second edition. By Joseph W. Bigger, M.D., Sc.D. Dub., Professor of Bacteriology and Preventive Medicine, University of Dublin. London: Baillière, Tindall and Cox. 1929. Pp. 452. 12*s.* 6*d.*

This excellent handbook has now reached its second edition and has been very completely revised. We confirm the favourable opinion expressed at its first appearance; it is one of the best students' text-books of bacteriology on the market. It is short, concise, and well written, and the author has succeeded in avoiding the sacrifice of essentials to brevity and the cramped, unreadable style familiar in books which have been too drastically cut down. At the same time we note that the present edition seems slightly fatter than its predecessor, and we trust that Prof. Bigger will sternly repress any further tendency to expansion, since in its present form and bulk the student can study the book at his convenience.

Food, Health, Vitamins.

New edition. By R. H. A. Plimmer, D.Sc. Lond., Professor of Chemistry in the University of London at St. Thomas's Hospital Medical School; and Violet G. Plimmer. London: Longmans, Green and Co. 1929. Pp. 120. 3*s.*

This is a new and considerably enlarged edition of the book by the same authors previously published under the title of "Food and Health." The expansion of the book has been made necessary by recent developments in our knowledge of the vitamins, and it now supplies in simple language a valuable summary of modern views on this subject. A new chapter has been added dealing briefly with the general principles of dieting in pregnancy, old age, and obesity. Two weekly menus for standard-sized families are included to illustrate how simple diets containing balanced quantities of the essential food constituents can be prepared at a minimum cost. The authors perhaps take up too uncompromising an attitude on the pathological consequences of minor degrees of vitamin B deficiency, since this question is still highly controversial. In other respects their book can be recommended as furnishing sound advice to the layman who wishes to know what kinds of food are most likely to promote his general well-being.

THE LANCET.

LONDON: SATURDAY, OCTOBER 5, 1929.

MENTAL HEALTH IN 1928.

> "Insanity is . . . only a disease like other diseases . . . and a mind diseased can be ministered to no less effectively than a body diseased. But the old conception of insanity dies hard, and its traces are still persistent. The modern conception calls for the eradication of old-established prejudices and a complete revision of the attitude of society."

THIS quotation from the Report of the Royal Commission remains the text of the Fifteenth Annual Report of the Board of Control, Part I. of which has just been published.[1] The sentence would provoke no dissent if the single-lettered word "a" were omitted. Insanity is disease like other diseases, but to call it "a" disease is to overlook the fact that it is nothing specific but due to a multitude of disorders of body and mind. Hospitalisation of all institutions for the mentally afflicted is the Board's great aim, although homes will still be needed for the chronic and infirm cases. Much has been accomplished; much remains to be done. Many institutions still fall short in greater or lesser degree of the standard set by the best, and the best could be still better. Many local authorities take a conservative position towards modern developments; while recognising the reasonableness of a cautious attitude towards new "cures," the Board feels strongly that in treating mental disease experiments should be made freely. Even if statistical results are disappointing, the patient and his relatives obtain an incalculable psychological benefit from the feeling that everything possible is being done, and that there is always hope. The only direction at present in which there is definite therapeutic advance is the malarial treatment of general paralysis, to which we referred in a recent issue[2] It is a regrettable and rather surprising fact that in all other departments of mental disease the average recovery-rate—30·84 per cent. for last year—has remained practically constant over a long period of years. This may be partly due to a higher standard of recovery nowadays, but whatever its cause, it must combine with the greater longevity of chronic cases, and the increase in general population, to produce a steady increase in the number of persons under care. The average annual increase of such persons is, in fact, just over 2000, and the total number on Jan. 1st, 1929, was 141,080. The Board points out that this increase by no means indicates an alarming increase in mental disorder, but it does mean a disquieting shortage of accommodation. To increase the number of beds in an existing institution, or to build a new one, may cost £500 per bed, and makes a heavy demand on the finances of the local authority. For this reason it is a true economy to spend money on the various hospitalisation schemes which make for the most intensive use of beds already available.

On this ground the Board strongly deprecates understaffing on either the medical or the nursing side, and welcomes the progress made during the year in the provision of restful and comfortable accommodation for nurses. It regrets the unsettled conditions of training in mental nursing and the difficulty of securing women nurses of good type and anxious to seek a qualification. It notes, however, the paradox that hospitals which set a high standard have the least difficulty in obtaining probationers. It urges the appointment, wherever possible, of a special occupation officer, citing the experience of the Dutch hospitals, Gantpoort and Maasoord, which emphasises afresh that there are many patients, including violent types, who benefit considerably and become far more amenable if trouble is taken to find the occupation best suited to the individual. This task demands experience, skill, and time, which an overworked medical and nursing staff cannot be expected to devote. Another measure which can be confidently expected to reduce the need for beds is a well-staffed out-patient centre. To overcome the foolish tendency to postpone treatment until concealment is impossible, the Board invokes the coöperation of the press. Adequate advance in new methods cannot be made without coördination, and the Report urges local authorities to encourage scientific research in such therapeutic reinforcements as ultra-violet and other light treatment, electrotherapy and hydrotherapy. Much of the work which is already being done would have its value greatly enhanced if the results were recorded under a uniform and approved schedule. A committee of the Medical Research Council is taking steps to associate certain mental hospitals in a scheme of this kind. The Board notes with pleasure an increase in the number of mental hospitals that are linked up with medical schools, for it feels that nothing could be worse for psychological medicine than any tendency to divorce it from other branches of medical study. Another development worthy of every encouragement is the organisation by the Royal Medico-Psychological Association of study tours of foreign hospitals. The Board suggests that a report of these tours by the Association would be of great value to those who are unable to participate in them. One suggestion coming from abroad is the appointment of a skilled psychiatrist as after-care officer. This experiment has been made with great success at Maasoord, Rotterdam, which has a markedly lower readmission-rate than other Dutch hospitals which have no such official. Another valuable appointment would be that of a social worker as almoner, to supplement the admirable work which is now done by the Mental After-care Association in tempering for the discharged patient the shock of return to a stressful and often temperamentally difficult workaday world. But when all is said and done it is the accumulation of the chronic insane, especially cases of dementia præcox, which constitutes one of the urgent social problems of the day. The cost and the wastage is terrific. Concentrated effort is needed—and will justify large expenditure of public money in research; research, that is to say, into causes, into a group of therapeutic methods, intensive experiment with occupation therapy, and any other kind of therapy, so long as conducted in a limited field and on lines that render it possible to estimate results. It would, we think, be worth while to offer valuable prizes for essays outlining details for research; not for the research itself, but for grounds for expecting useful results from further study. The public wants awakening to the gravity of this problem.

The outstanding events of the year in the field of mental defect were the passing of the Local Government Act and the publication of the Report of the Mental Deficiency Committee. The Board's Report reviews the relevant sections of the Act and points out the benefits which may be expected to result from uniform control. It is hoped that both ascertainment and classification will be greatly improved. The figures given in the Wood Report make it highly probable that the increased accommodation made available by the Act will still be inadequate. The older type of poor-law institution is only suitable for the untrainable and unemployable classes, but a great many defectives of this type are still occupying space in mental hospitals, and their transfer to a poor-law institution would release beds urgently required for curable cases of mental disease. For the educable defective new colonies are still badly needed, and little was done during 1928 to meet the shortage; Hampshire and West Riding County Councils opened new colonies, and three other new institutions also became available. Several designs for big schemes are now, however, well advanced, and the Board is of the opinion that every local authority ought to have a central colony or a share in a colony where there is enough land for workshop and field employments and recreation. Although the actual amount of new accommodation—625 beds—falls so short of urgent requirements, yet it is nearly double that of 1927, and a large number of local authorities are taking steps in the face of many difficulties to fulfil their statutory obligations. While taking a guarded attitude towards sterilisation, the Board definitely recommends the prohibition of marriage of defectives. Shortage of accommodation, therefore, the key-note of the reports on mental deficiency for many years past, is still the principal trouble to-day, and has extended to mental hospitals also. Most of the hospitals are overcrowded and many have already been expanded to the uttermost limit. The position is serious; a modern mental hospital takes time to design and construct, and no local authority can afford to postpone serious efforts to meet the problem until the strain on their existing hospital has become acute.

CURES AND PREVENTION.

THE author of a new American handbook on "The Common Head Cold and its Complications"[1] explains that if the information he has to offer is not altogether satisfactory "it is because our scientific knowledge is not in all respects final." As Regius Professor of Medicine at Oxford Sir FARQUHAR BUZZARD would doubtless agree with this statement, but in the address published on p. 695 he suggests that we know enough about colds to feel hopeless about them. The common cold is not curable, he said; and as for prevention, the necessary measures would be so troublesome and onerous that the public would never put up with them. He advised his audience (in the manner of Mr. BELLOC) to answer, as they took their fees, there is no cure for this disease, Henry will very soon be well.

While it is quite true that the symptoms of infectious diseases are mostly the signs of a battle between parasite and tissues, we cannot agree either with his statement that "all the material facts about" the common cold are already known, or with his pessimistic outlook that no cure for that complaint will be found as relatively effective, for example, as antitoxin in diphtheria. It seems evident that there is some "material fact" about these infections of mucous surfaces which has not yet been ascertained. No one so far has hit upon any theory or any empirical procedure which will enable us to kill the microbes or prevent their injurious action on the tissues. But no cheerful believer in the intelligence of man can seriously doubt that there is a solution somewhere. Bacteriology is only just getting into its stride and immunology has hardly begun to totter on its first steps; the golden age of catarrhs is surely only just round the corner.

Meanwhile what is to be done? Sir FARQUHAR BUZZARD urges very truly that if we cannot cure a disease we should give our minds to prevention, and that we should frankly recognise that some conditions, such as the paralyses of poliomyelitis, are in effect incurable. With such doctrine no one can possibly quarrel. Medicine has always put prevention in the front of its programme, its main triumphs are hygienic rather than therapeutic, and it is along these lines that it will progress. But it remains true, and probably will always remain true, that the daily work of the medical man will be chiefly therapeutic. Prevention will sometimes fail, and the diseases of old age are, as far as we know, unpreventable; with our ageing population they will become relatively more frequent. One has, too, to recognise that a man or woman who is incurably diseased is by no means as good as dead. From their own point of view, and often enough from the world's point of view, they are as much alive as anyone else, and much of the kindly art of medicine will, we hope, always be devoted to making the rest of their pilgrimage as easy and effective as it may be. It is questionable whether medical men ever do anything more really useful, though the theory and practice of helping those who are irretrievably maimed does not perhaps play any large part in our curriculum. Medicine is not wholly materialistic: it would discharge its functions sadly if it had nothing in view but a healthy body. Let us have that by all means if we may, but if we cannot let us bear in mind that comfort and cheerfulness do many people good besides the sick man. When prevention and cure have failed, there is much left to do which is worth doing.

WORLD HEALTH ORGANISATION.

COMPETENT observers of the Tenth Assembly of the League of Nations have detected in its proceedings an unusual insistence on active progress and increased achievement. The note was heard in all directions, not only on the promotion of peace and disarmament, but in the discussions of such diverse matters as tariff barriers, international communications, child life protection, control of drugs of addiction, and even the internal organisation of the secretariat. Among them the Health Organisation of the League—a term which includes the medical director and his staff, the health committee, and advisory health council—came under review in its place. If we may judge from the discussion of its work in the Second Committee, reported in the *Assembly Journal* of Sept. 18th, and by the subsequent approval by the Assembly of the report submitted to it by the Czecho-Slovakian delegate, Mr. FIERLINGER, it emerged not only with credit, but with as much enthusiasm as the Assembly can be expected to show over an undertaking which has so far gone its way without producing political repercussions or national controversies. The output of the Organisation in terms of its publications continues to grow, while the steady increase in the variety of subjects with which it deals is made evident when the last annual report of the medical director is contrasted with those which he presented only a few years ago. The compilation and issue of returns about notified infectious diseases and similar data from the different countries of the world continue both at

---

[1] By Walter A. Wells, A.M., M.D., F.A.C.S., Professor of Otolaryngology, Georgetown University, Washington, D.C., with an introduction by Hugh S. Cumming, M.D., Surgeon-General United States Public Health Service. New York (obtainable in England from Messrs. Macmillan & Co., Ltd.). Pp. 225. 10*s*. 6*d*.

Geneva and at the branch health office of the League in the Far East, which has been established at Singapore. The International Health Year-book, comprising notes of the principal happenings in different countries, has taken a new form and its last issue has been so enlarged that it makes quite a formidable volume of reference. New handbooks have been prepared regarding vital statistics and the public health administration of different countries.

In the more important field of international expert study some notable contributions have lately been made to the science and practice of preventive medicine, particularly the reports of the International Conference on sleeping sickness[1] and on the radiological treatment of cancer of the uterus.[2] To these should be added a comprehensive survey which has just appeared of the measures taken in different countries for the welfare of the blind. The rapporteur laid special stress on the progress of combined investigations into particular aspects of syphilis, malaria, and the causes of infantile mortality. The successive conferences on the first subject have focused national studies of the technique of serum reactions, and have undoubtedly led to greater accuracy and comparability of all the diagnostic tests employed for syphilis. A similar comparison of the efficacy of modern preparations in the treatment of this disease is now proceeding on a large international scale. The inquiries which have been pursued by the Malaria Commission, extended in the present year to India, have resulted in a series of authoritative reports which are doing much to determine the wise selection and economic application of different antimalarial measures according to the circumstances and resources of the countries affected. In the case of infantile mortality a standard pattern of inquiry has been set up which each country can adopt, and those countries which have already adopted it have found that it affords an invaluable guide and stimulus to national effort. Claims such as these made on behalf of the League's work are substantiated by the facts, and their recognition should be gratifying to the medical officers of our own Ministry of Health and other British technical representatives who have not only taken their share in the conferences and committees, but themselves have provided a very essential part of the material and research which has made these several investigations fruitful. In the debate in the Second Committee some delegates advocated the still greater increase of investigations of this kind—for example, the institution of an intensive world study of influenza—while others hinted at the danger of the Health Organisation trying to do too much without a more systematic programme. Both contentions have force, but provided the inquiries are well thought out by the responsible body, the Health Committee, before they are put in hand, and the principle is followed that there should be only one quality of work—the best—their increase should be universally welcomed.

At the Assembly the public health work of the League has now come to make an exceptional appeal on the ground of the universality of its application. While disarmament, tariffs, and opium control affect some nations vitally but leave others indifferent, there is no country in the League which cannot benefit by consultation on one or other of its health problems. In some instances it is evident that these are political and administrative rather than purely technical. The recent application of Greece to the League for a Commission to advise on the reorganisation of its sanitary services is an instance in point. This Commission, of which Sir GEORGE BUCHANAN was the British member, laid down a scheme which the Prime Minister of Greece informed the Assembly that his Government has already adopted. In pursuance of it the services of one of the principal medical officers of the League, Dr. NORMAN WHITE, have now been lent to the Greek Government, while Mr. VENIZELOS himself, in order to further the scheme, has added the portfolio of a Minister of Health to his other offices. The League has just received a similar request from Bolivia for advice on the organisation of its health administration; while much attention was attracted at the Assembly to communications received from the Government of Nankin, as a result of which the medical director, Dr. L. RAJCHMAN, with other members of the secretariat, will almost immediately visit China and the Chinese ports. The Assembly indicated its satisfaction with the principle of these requests by voting a special credit for the purpose, additional to the normal public health budget and to the income furnished by the Rockefeller Foundation. From the point of view of hygiene, as well as of its effect in extending the influence of the League of Nations, the results of these new and highly responsible undertakings will be followed with attention and interest.

◆

BRITISH COLLEGE OF OBSTETRICIANS AND GYNÆCOLOGISTS.

THE Board of Trade has approved the scheme submitted for its approval last March, and on Sept. 13th the incorporation of the British College of Obstetricians and Gynæcologists was completed and with it the inauguration of a movement for the advance of the twin sciences of obstetrics and gynæcology which should turn to great good. Chief among its objects is the design to increase the prestige of this branch of medicine, to provide a better training and a severer test for medical students in these subjects, along with fuller opportunities for learning them. In giving our support to the movement in the spring we pointed out then what compelling force was given to it by the continuance of the high rate of mortality in childbirth. We recognised in passing the validity of the practitioner's plea that it is economically impossible for him to follow out the rules which his teachers impress upon him for the conduct of labour. These are evils whose roots go deep into social problems, but the work of the new College should be helpful in their solution. Following on the incorporation of the College the first meeting of the Council was held in London on Sept. 25th, when Prof. W. BLAIR BELL (Liverpool) presided and the following were elected members of the first general Council. For London: Dame Louise McIlroy, Dr. T. Watts Eden, Dr. J. S. Fairbairn, and Mr. L. C. Rivett. For the Provinces: Prof. A. Donald (Manchester), Sir Ewen Maclean (Cardiff), Prof. Carlton Oldfield (Leeds), Prof. M. H. Phillips (Sheffield), Prof. Beckwith Whitehouse (Birmingham), Dr. Farquhar Murray (Newcastle), and Mr. Leyland Robinson (Liverpool). For Scotland: Prof. R. W. Johnstone (Edinburgh), Prof. Munro Kerr (Glasgow), Dr. W. F. T. Haultain (Edinburgh), and Dr. R. A. Lennie (Glasgow). For Ireland: Prof. C. G. Lowry (Belfast), Dr. Bethel Solomons (Dublin), and Dr. T. M. Healy (Dublin). Under Article 40 of the Constitution the following were coöpted on the Council for the purpose of organisation—

viz., Prof. R. J. Johnstone (Belfast) and Dr. Eardley Holland (London). Proceeding to the election of officers, Prof. Blair Bell was chosen president, Prof. Munro Kerr vice-president, Mr. Comyns Berkeley (London) treasurer, Prof. W. Fletcher Shaw (Manchester) and Dr. H. Russell Andrews (London) secretaries. Sir Francis Champneys was appointed vice-patron of the College in recognition of his service to obstetrics and gynæcology, and especially to the College during the process of its formation. Finally, the following were elected members of the Executive Committee—viz., Prof. Blair Bell, Mr. Comyns Berkeley, Prof. Munro Kerr, Mr. Rivett, and Prof. Fletcher Shaw.

Annotations.

"Ne quid nimis."

MEDICAL DEFENCE.

THE tendency of recent years to add more and more scientific tests and standards to the practice of medicine has had at least one real disadvantage to the medical profession. It has made it increasingly difficult to get patients to appreciate the fact that medicine can never be an exact science. They are every year more apt to judge the results of treatment by an arbitrary and sometimes grotesque standard, usually infused by natural but undue optimism. If the standard is not reached they promptly blame the doctor, and woe betide him if he has omitted to call in the aid of any modern scientific measure applicable to the case. The absolute necessity of a precautionary X ray in any case of injury which might conceivably involve fracture has been urged again and again, yet Sir Herbert Waterhouse, in his presidential address at the annual general meeting of the Medical Defence Union on Thursday of last week, had to report once more that most of the cases causing his Union anxiety had been those involving failure to advise radiography. "Unless we are in a position to prove," he observes, "that such advice has been given, the defence of our member becomes a matter of great difficulty or even impossible." There are, however, other risks attendant upon the practice of medicine. As the solicitors, Messrs. Hempson, point out in their report, there is the unscrupulous type of person who thinks that he may escape payment if he only voices his dissatisfaction loudly enough and threatens to charge a professional man with negligence. Against such there is no immunity, either in consulting work or in the public health service. There is also the possibility in public health or other whole-time employment of disputes with employers or complaints by ratepayers or other members of the public. The risk is certainly in the minds of a growing proportion of the profession, and we are glad to learn that the membership of the Medical Defence Union now stands at 15,045 and that its financial position has never been better. Its work covers a very wide range of service to medical men and women; defence against action plays a relatively small part. The counsel of experienced advisers can often avert proceedings, and prompt attack may be the best form of defence. The Union may be said to handle every variety of difficulty connected with the practice of medicine. Perhaps the most outstanding case of the year was that, reported in our columns at the time,[1] in which a medical man was held liable for the hire of a car ordered by him for the transport of a patient. This was one of the two cases in which the Union suffered defeat, and at any rate should do service to the profession by calling attention to the importance of disclaiming personal liability when giving an order on behalf of a patient. In the other case the failure was due to the injudicious conduct of the member after action had been threatened; this illustrates again the importance of consulting the Union early and of abiding faithfully by its advice throughout. Another feature of the year's work was the action taken to maintain the professional standard by referring to the General Medical Council the conduct of certain registered practitioners. In every case the Council found the charge proved, and in one case ordered the removal of the name from the Register. More cases than usual have been settled out of court because the Union had no hope of successful action. There were nine of these cases: two involved the loss or partial loss of the sight of one eye, one owing to instillation of the wrong drops and the other to leakage of anæsthetic; three were cases in which a swab or instrument had been left in the body at operation; one patient had been burned during treatment by diathermy; in two cases there were obviously mistaken diagnoses under circumstances in which it might have been difficult to prove that reasonable skill and care had been exercised, and in the ninth case the practitioner had been carried away by sympathy for relatives and had signed an urgency certificate without actually examining the patient. The policy of the Union, however, is strongly opposed to the settlement of claims out of court, and every possible avenue of defence is thoroughly explored before compromise is admitted. In the last 15 years 1641 cases have been handed over to the solicitors by the Council of the Union and the total cost of subsequent litigation was £14,076. In the 63 heaviest cases the average cost per member was about £381. It seems almost incredible that there are still thousands of practitioners who are unwilling to pay £1 a year or a life sum of £25 to insure against this risk. In the words of the solicitors: "It is no exaggeration to say that no medical man is free from this risk, and that every case he attends is a source of possible danger... however small the risk the results may be disastrous and peace of mind is cheap at £1 a year." Membership of one of the defence societies is the only way of securing it.

FLUKE INFECTIONS OF MAN'S BILIARY PASSAGES.

DURING the past year some significant observations have been made in Russia on infection by flukes of the bile-ducts and gall-bladder of man. P. Sdrudowski, of Baku, on the Caspian Sea, and his assistant, F. Jaguboff, have reported that, in fæcal examination of 900 persons, ova of liver-dwelling flukes were found four times—those of *Fasciola hepatica* and those of *Dicrocoelium lanceatum* each being noted twice. All four patients had such hepatic symptoms as jaundice and a large and tender liver. K. Plavtov, of Nakhi-Chevan, at the head of the Sea of Azov, reports on a herdsman who passed eggs of *F. hepatica* without symptoms, and on eight other persons passing those of *D. lanceatum*, of whom one at least was ill with an intense anæmia, but without anything to point to the liver as a seat of infection. Again, N. Karibow, of Tiflis, saw two boys of about 11, from different Georgian provinces, of whom one was without symptoms and the other suffered from biliary colic, while in both the eggs of *F. hepatica* could always be found not only in the fæces but by duodenal catheter. Since in most of these cases where fluke's eggs were discovered symptoms of hepatic disturbance were present, there is little doubt that true parasitism existed. That this *need not be so is evident from observations* by S. M. Koulaguine,[1] who was struck by finding that of 40 persons in whose fæces he found eggs of these parasites, 38 seemed perfectly healthy. He suspected, therefore, that the trematode eggs which he had seen had been swallowed with food, and he was indeed able to observe instances in which a meal of boiled liver infected by these two flukes resulted in the evacuation of their eggs in the fæces over the next three or four days. He confirmed this observation on his own person, having first satisfied himself that he was free from the infections. Even when liver was boiled, roasted, or baked the eggs appeared to be unaltered, and it may be concluded that with imperfect cooking eggs may be passed alive in the fæces of the man who has swallowed them. It is clear, then, that when hepatic symptoms are absent a diagnosis of infection by these flukes, based on the finding of their eggs in the fæces, may well be a mistake. They should be sought for repeatedly by duodenal catheter, unless the ingestion of infected liver can be completely excluded. This observation should bring about a careful scrutiny of cases of supposed infection by these occasional parasites of man.

PERCEPTION OF MOVEMENT.

IT is supposed by some that the perception of moving objects, together with a crude light sense, represents a primitive type of vision, in some respects differing from the vision of stationary objects. In order to throw light on the problem some experiments have been carried out [1] by Mr. Myer Salaman, M.A., on the vision respectively of moving and stationary objects in the periphery of the visual field. The first experiment was planned with the object of discovering whether, when a moving object is observed peripherally, a perception of discontinuous change of position is ever obtained without perception of movement. An apparatus was employed by means of which the speed of a horizontally moving object and its angle of eccentricity could be exactly regulated, and numerous reports were obtained from six trained observers. All observers complained of the extreme vagueness of the perceptions, but the majority agreed in reporting change of position of the spots at eccentric angles at which no movement was perceived. This applies most decidedly to slow movement of under 0·2° of visual angle per second. When the rate of movement was more rapid it was, of course, more easily perceived. A second experiment had for its object to discover whether discontinuous change of position of an object, observed peripherally, is ever perceived as movement. In this experiment half of the observers never obtained any illusory perception of movement at all. Of the rest the only ones who gave any but negative results were those who had knowledge of previous work on the subject and of the nature and purpose of the experiment. The conclusion suggested is that the illusory perception of movement was in these cases subjective and psychological, not the outcome of any physiological process connected with the retina. The author is far too cautious to deny what others have maintained—that there may be a special physical basis for the visual perception of movement, but at any rate he shows that no conclusions can be drawn from experiments on the subject in which the psychological factors are ignored.

THE DOSAGE OF INTRAVENOUS GLUCOSE.

THOUGH intravenous glucose is recognised as a serviceable agent in conditions of exhaustion, toxæmia, or dehydration and is widely used, dosage and general technique are apt to be rather casually determined. Dr. P. Titus and Mr. H. D. Lightbody, working in the Department of Obstetrics and Gynæcology of the St. Margaret Memorial Hospital at Pittsburgh, set themselves to ascertain the quantity, concentration, and rate of injection of glucose which would yield the best results. They were chiefly concerned with the toxæmias of pregnancy and sundry gynæcological conditions, but their conclusions[2] have wide medical and surgical applications. They plead at the outset for as much care in calculating the dose and in controlling the administration of intravenous glucose as is used in the giving of any potent agent. They attribute clinical failure and "reactions" to faulty technique or dosage, and remark that ill-effects would certainly be observed if in morphine therapy the dosage was casually arrived at anywhere between grs. 5 and one-hundredth of a grain. To establish their data the authors seized on the cardinal fact that intravenous glucose causes a rise in blood-sugar up to a certain point, with a subsequent sharp and inevitable fall. This fall is, of course, of the highest importance, since hypoglycæmia is probably the cause of the convulsive reactions reported from time to time. It is almost certainly due, according to the charts presented, to an over-stimulation of the pancreas by the excess glucose and an over-production of endogenous insulin. Proceeding along clinical experimental lines the authors tackled separately the three problems of quantity, concentration, and rate of injection. The first consideration is the therapeutic dose. As a general rule probably too little is given. Indeed underdosage, combined with a too rapid rate of injection, may well account for the disrepute into which glucose falls from time to time. On the other hand, overdosage will lead, as has already been stated, to a paradoxical hypoglycæmia with the possibility of convulsions. It seems that the best quantity for an average sick adult is 75 g. The concentration of the solution should be decided upon after a review of the clinical condition. For example, in pneumonia when the patient has a weakened heart muscle, strongly hypertonic solutions should be chosen, so as not to overload or strain the right ventricle; while in a case of dehydration from vomiting and diarrhœa a weaker hypertonic solution is preferred. It will surprise many English readers to learn that 50 per cent. is recommended for the stronger, 10 per cent. for the weaker solution. For the rate of injection the authors fall back on the determinations of R. M. Wilder and W. D. Sansum,[3] who concluded that the rate should not exceed 0·8 g. of glucose per kilo of body-weight per hour. This is very much slower than the rate used in many hospitals and the disadvantages of rapid injection should therefore be emphasised. A certain sequel is the immediate loss of the substance by heightened urinary excretion before it has had time to act; a probable sequel is an over-stimulation of the pancreas, leading to endogenous over-production of insulin similar to that following overdosage. According to Dr. Titus and Mr. Lightbody, a basis for the administration of glucose to adults should be 75 g. of glucose in 300 c.cm. of water given over a total period of one and a half hours. The injection need not be continous but may usefully be given by instalments throughout the day. In children proportionately smaller quantities of sugar should be given but the time of injection should not be reduced.

CHANGES IN LOCAL GOVERNMENT.

THE end of September saw the expiration of the period allowed to the county councils and county borough councils for the formulation of their plans for taking over the public health and administrative work of the boards of guardians. On the last day of March next those bodies will automatically be dissolved and their successors will receive a large addition of dignity and importance, tempered by the obligation to perform extensive and often complicated functions familiar, in most instances, to a minority only of their members. So great a change in our system of local government entails careful and minute arrangements for smooth working, but in the main they must necessarily bear a family likeness. To what extent they differ it is impossible to say, since many scores of schemes have had to be prepared. The general outlines are, however, familiar. From April 1st the councils of counties and county boroughs —that is to say, all the great towns, and some that are not so great—will be responsible for poor-law finance, indoor and outdoor relief, and the maintenance of poor-law institutions, so long known as workhouses, and poor-law infirmaries.

This is a heavy load of work to place upon the shoulders of authorities which grow busier every year, but the Local Government Act of 1929 provides for it to be met by delegation. Even as the councils appointed education committees when they took over the functions of the school boards, so will they now appoint public assistance committees that will absorb the paid officials of the guardians. These bodies will have the general supervision of all poor-law work, subject, of course, as the education committees are, in matters of principle, to the approval of the councils. The composition of these committees is of great practical importance. They may consist only of elected councillors, and in some places that course has been followed, or they may include coöpted persons to the extent of not more than one-third, some of whom must be women. The borough public assistance committees may and, as a rule no doubt will, appoint subcommittees consisting mainly of elected councillors, but here again, if outsiders are coöpted, women must be among them. In the counties subcommittee are compulsory, for the obvious reason that it is impossible to administer relief from a single centre. These guardians' committees will do work for which local knowledge is necessary, such as interviewing and investigations. They will consist of members of the subsidiary councils, in the area, nominated by those councils, members of the county council representing the area, and male and female coöpted members—this is compulsory—to the extent of not more than one-third. The inclusion in this category of as large a number as possible of the old guardians and others with poor-law experience is very necessary, and even where elected councillors only have been chosen it is probable that some of them are, or have been, members of boards of guardians.

[3] Arch. Int. Med., 1917, xix., 311.

It is probable that, in most instances, the difficult and complicated question of the most effective means of coöperation between the poor-law hospitals and the voluntary hospitals has, as yet, been settled only in broad outline, even if so much has been done. The details of such coöperation are necessarily intricate, and whatever is arranged must needs be subject to the test of experience. The primary object must be to prevent waste and overlapping, and that crowding of one institution while a neighbouring one has beds to spare which has been so serious a weakness of the old system. Not less important will it be to create something like a uniform standard of efficiency, which was virtually impossible so long as we had two hospital systems existing side by side, one of which was, so to speak, under a cloud. From the point of view of the public health the councils have a great opportunity and, with goodwill on both sides, the voluntary hospitals ought to be the stronger for the adoption of rationalisation in quite a new sphere.

ANAEROBIC TOXÆMIA IN ACUTE OBSTRUCTION.

MICRO-ORGANISMS, like people, have their phases of popularity. The bacillus of gas gangrene, for instance, was long regarded as of no significance except in foul wounds, but M. Weinberg,[1] in France, followed by B. W. Williams[2] in this country, has endeavoured to establish its importance in acute intestinal conditions, and in America it is being advanced as a cause of pernicious anæmia. As regards its action in obstruction of the intestine and acute peritonitis, Weinberg has urged that it produces an infection, and Williams that it forms toxins which are absorbed. In a case lately published by J. Sailer, G. M. Laws, and J. Eiman[3] the afebrile collapse of a woman patient after appendicectomy suggested to the authors the toxæmia of "gas gangrene." On her death *B. welchii* was found in the small intestine and proved lethal to rabbits. The reporters of this case apparently believe it to be unique, but it is of the type described again and again by Weinberg and Williams. The whole theory of the absorption of this toxin from the gut in acute obstruction has lately been traversed, however, by A. W. Oughterson and J. H. Powers,[4] who have repeated Williams's experiments on a much larger scale. Eleven dogs were given acute obstruction and the contents of their small intestines were filtered and injected into the peritoneal cavity of mice. An equal number of mice received the filtered intestinal contents plus a *B. welchii* antitoxin of established quality, and the results seemed to be quite arbitrary. Few mice died, protected or unprotected; in many cases more protected mice died than unprotected. A second series of dogs were then given acute obstruction and the intestinal contents were this time injected into rabbits. It was hoped to find evidence of anti-hæmolysin to *B. welchii* hæmolysin, if it was present, and as a control a sample of known *B. welchii* toxin was similarly injected. The results were negative, however, save in the control rabbit. Lastly, cats were given acute obstruction, and it was found that no relief of symptoms was afforded in the group to which antitoxin was given. The usefulness of the antitoxin treatment of acute obstruction in practice has been emphasised by many writers, including J. O. Bower and J. Clark,[5] but the original theory of intestinal absorption requires confirmation before it can be held to be established. The therapeutic value of the method has not so far been denied in any publication, but the theoretical basis of the method, already resting on two contradictory arguments, is decidedly uncertain.

THE RIPENING OF BEEF.

IT is estimated that those English butchers who supply the wealthier classes sell only 25 per cent. of a beef carcass for roasting purposes, the remainder being destined for stewing, boiling, or pickling. In industrial districts over 54 per cent. of the carcass is sold for roasting, the cheaper and usually tougher joints, such as silverside, topside, aitchbone, and middle ribs, being disposed of for this purpose as well as the sirloin and fore-ribs. It is obviously desirable that the palatability of the cheaper joints should be raised to as high a standard as possible. With this end in view the Department of Scientific and Industrial Research recently undertook an investigation on the effect of hanging, or conditioning, upon the palatability of meat, and their report on the subject has just been issued.[6] The investigation consisted essentially in a comparison of the palatability of samples of hot and cold roast beef derived from carcasses which had been stored at suitable temperatures for varying lengths of time. The palatability was assessed by teams of experts who allotted marks to each sample for such qualities as tenderness, flavour, texture, juiciness, and colour. Joints from one-half of each carcass were cooked and tasted three days after the slaughter of the animal; the other half of the carcass was stored at a temperature of 41° F. for a further 4 or 14 days, after which interval corresponding joints from this half were similarly cooked and tasted. In almost every case there was a marked progressive improvement in the palatability of the samples with the increase in the period of storage, due mainly to an increase in tenderness. The increase in tenderness was more pronounced with the coarser joints than with those of the first quality, and was sufficiently constant and striking to lead the authors of the report to suggest a scheme for the conditioning of beef at central depôts such as municipal abattoirs. Under such a scheme the dressed carcasses would be cooled for one to two days at a temperature of 31–33° F. (short of actual freezing) and then stored for 10 to 12 days at a temperature of 36–38° F. Before removal to the retail shops, or at least before being cut up into joints, the carcasses should be stored for about 24 hours at ordinary temperature, or in summer at some controlled temperature round about 40–45° F. The possible objections to a procedure of this kind, such as increased liability to putrefaction and diminished attractiveness of the joints by loss of bloom and sweating of the surface, are shown to be without foundation, providing due attention is paid to the temperature and degree of humidity of the storage chambers. Now that it has been proved that beef, and especially the cheaper cuts, can be rendered more palatable by the process of ripening or conditioning, what chance is there that this process will be applied generally to the meat prepared in this country? The first and most important step in this direction is the creation among the public of an appreciation of conditioned meat and a demand for it. In the opinion of the writers of the report the coöperative societies have unique opportunities for educating the public in this matter, for in the majority of cases they already possess, or contemplate the erection of, abattoirs fitted with cold storage accommodation where the conditioning could be carried out. Every member of the meat-eating population who is informed of the facts could help to create the necessary demand by reiterated requests to his own butcher for the supply of conditioned meat.

THE RADIUM COMMISSION.

It is now six weeks since the Radium Commission was appointed, and although the holiday season has intervened good progress has been made with work preparatory to the important matter of distribution. It is unlikely that more than three grammes of radium will be available in suitable containers before the end of the year, and it will task the National Physical Laboratory at Teddington, to which the supplies are to be consigned for safe keeping, to test and measure this quantity. In addition it is hoped that a loan of four grammes in the form of a so-called bomb may be available on loan from the manufacturers, in the same way as the Haut-Katanga Mining Company has for a long time past loaned to the Institut du Radium and other research centres in Paris a large quantity of the radium element at its disposal. No decision has yet been taken as to the particular institutions to which the radium will be distributed, although it has been agreed in principle to give preference to centres where treatment is combined with teaching and research. The Commission will, of course, require detailed and uniform records to be kept of the use to which the radium is put, especially as the loans will be made on terms which will simply recoup the Commission for the expenses incurred. Prof. Sidney Russ, D.Sc., has been appointed scientific secretary to the Commission, the offices of which are at 5, Adelphi-terrace, London, W.C. 2, where communications should be addressed to the secretary.

THE SEQUELS OF TOXÆMIC PREGNANCY.

It used to be said at one time that there is no great risk of permanent damage after a toxæmic pregnancy, and as recently as 1924 Whitridge Williams in his book, "Obstetrics," stated that one attack of eclampsia *confers immunity against further attacks* in subsequent pregnancies. Among writers who have lately contradicted this is C. H. Peckham,[1] who found that 23 per cent. of 77 cases of eclampsia treated at the Johns Hopkins Hospital had chronic nephritis when examined a year later. Equally remarkable figures have been brought forward by James Young[2] in Edinburgh and by G. F. Gibberd[3] at Guy's Hospital. Young found that more than half the pregnancies which followed a toxæmic pregnancy were pathological, but noted that the incidence of chronic nephritis after a toxæmic pregnancy was low—namely, 3 per cent. after eclampsia and 8 per cent. after albuminuria. He rejects the common view that there is a definite type of toxæmia, sometimes called the nephritic type, and he thinks that all types of late pregnancy toxæmia may be recurrent. Dr. Jessie Sym in our present issue records a further investigation of the series of cases that Young examined, and gives some more statistical details. These show that the danger of subsequent toxæmic pregnancy is considerably greater after "albuminuria of pregnancy" than after eclampsia; thus she finds that 27 per cent. of subsequent pregnancies after eclampsia are toxæmic and 49 per cent. after albuminuria—not to mention many others in which abortion takes place in the early months. Twenty-five of the women in Peckham's series were under observation in their next pregnancies and 14 (56 per cent.) of these proved pathological. Gibberd regards all first attacks of albuminuria in previously healthy patients as due to a primary toxæmia, any renal insufficiency being purely secondary. In estimating the fate of ten such patients he says that one will suffer so much damage to the kidneys that she will develop a frank chronic nephritis, whilst four will recover their renal function completely and afterwards have normal pregnancies. The remaining five—i.e., half those who originally had toxæmia—will, he thinks, have a recurrence of albuminuria fairly consistently with all subsequent pregnancies. Although their kidneys are not obviously damaged they have nevertheless a permanent occult nephritis and will show signs of insufficiency when put to the strain of pregnancy—"the most delicate test of renal function that we possess." It has been shown that the length of time the initial toxæmia lasts is of considerable importance *in deciding whether occult nephritis will follow*, and although, as Gibberd rightly points out, "this is not the whole question," it is reasonable to conclude that signs of toxæmia during pregnancy should be treated energetically without delay. Failure to react to treatment is an indication for ending the pregnancy, whilst in future pregnancies the prognosis must obviously be guarded and careful watching of the patient will be required.

A CHAPTER IN PUBLIC HEALTH.

Dr. Philip Boobbyer's retirement after 40 years of strenuous work for the citizens of Nottingham is a noteworthy event in the history of British public health. The first half of his tenure of office belongs to the period when sanitation was chiefly environmental and directed towards improved conditions of life for the community as a whole. The report, which he has just issued, deals with the last 18 years during which the measures for the benefit of individual health have taken form. The original maternity and child welfare centre was established in Nottingham early in 1908 by voluntary agency with material assistance from the municipality, and was second only to the St. Pancras centre opened in the previous autumn. Here, as elsewhere, the voluntary scheme assumed official status, and now nearly 50 per cent. of the children born in the city come into touch with the welfare centres and about 10 per cent. of the expectant mothers attend the antenatal clinics. Dr. Boobbyer pays a tribute to the midwives who attend 70 per cent. of the births, and notes the fact that the civic authority does not yet provide or subsidise maternity hospitals. Since 1921, however, no baby has been totally blinded by ophthalmia neonatorum, although 12 cases of impaired vision from this cause have been reported. Antituberculosis work began in Nottingham with the provision of beds at the isolation hospital in 1903 and culminated in the establishment of a tuberculosis dispensary and the appointment of a tuberculosis officer in 1913. The mortality from tuberculosis in the city has fallen by nearly one-half during the last 50 years, the drop being continuous except for the war years, when the setback was chiefly among adult females. In 1928 the deaths from tuberculosis numbered only 8·5 per cent. of the total deaths, and existing institutional accommodation may be regarded as adequate except for advanced cases. Dr. Boobbyer considers that the venereal disease scheme has reduced the prevalence of syphilis in Nottingham by more than 52 per cent. but he attributes the lesser grade of success with gonorrhœa to the growing laxity of public morals and the lack of a specific remedy. Since the war the Nottingham Corporation have built or ordered 7000 houses and cleared or adopted schemes for the clearance of nearly 28 acres of slum property. From 1868 to 1912 Nottingham was a pail-closet town; in April, 1912, it was decided to adopt water-carriage, and by the end of 1923 all the 40,000 pail-closets had been converted. The water-supply, which used to be entirely from deep wells and borings in the Bunter sandstone, with a total hardness of 18·4 degrees, has been supplemented to the extent of 33 per cent. by a soft moorland supply from the head waters of the Derwent. The new sewerage, when completed, will render Nottingham one of the best-drained cities in the country; a public abattoir and a crematorium are in prospect. Dr. Boobbyer describes the special activities of the war years; how the comparative freedom of the civil population from infectious diseases enabled much hospital accommodation to be put at the disposal of the War Office; the provision of war creches for the children of munition workers, and temporary expedients such as delousing stations and a venereal diseases prophylactic centre for the allied troops. The outbreak of mild small-pox in 1921–22, 113 cases with no deaths, is attributed to the visit of seven Mormon missionaries from Utah. Nottingham has been less severely attacked than many towns by encephalitis lethargica; 74 cases with 27 deaths occurred in 1924–26. Only two cases of post-vaccinal encephalitis have come to Dr. Boobbyer's knowledge since 1920. The survey should interest both Nottingham citizens and others.

BLOOD-PLATELETS IN WERLHOF'S DISEASE.

THE conception of the "morbus maculosus of Werlhof" as an essential thrombopenia has attracted a great deal of attention since it was introduced some years ago by Frank, and has largely influenced the treatment of hæmorrhagic states. The suggestion is that the basis of this particular manifestation of the hæmorrhagic diathesis is a shortage of platelets, either acute or chronic. It was as a result of the observation that splenectomy, both in man and animals, is followed by an increase of the platelets that Kaznelson recommended and practised the surgical removal of the spleen in this condition, and many cases are now on record in which this operation has been followed by the happiest results, though in others it has been a failure. Faith in the theory on which the operation is proposed has been somewhat shaken, however, by the observation that even in cases in which hæmorrhages cease after splenectomy the platelet count, after an initial rise, often returns to its original low level. The whole question has recently been reconsidered by Prof. Roskam, of Liége, who records[1] cases clinically characteristic of Werlhof's disease in which there was no diminution of the platelets, and on the strength of this observation calls into question the whole of Frank's conception of the pathology of the disease. Roskam draws attention to the frequent presence of the "brassard" sign—namely, the occurrence of petechial hæmorrhages after constriction of the arm by the brassard of a sphygmomanometer at a pressure between the systolic and diastolic. This he regards as evidence of capillary damage, and he points out that the amount of hæmorrhage produced in this way may be different in the two arms, which suggests that one portion of the body may be more affected than another. Eventually he comes to the conclusion that Werlhof's disease is more correctly regarded as a disease of the vessels than of the blood itself. That there may be concomitant thrombopenia he does not deny, but he looks on it as secondary to the vascular lesion and not causative of the hæmorrhages. No attempt is [illegible] this paper to explain the beneficial results of [illegible] certain cases. It is evident on present knowledge, however, that the original hypothesis of Frank cannot be retained in its entirety, and that the whole question of the hæmorrhagic diathesis and the rôle of the platelets in its causation is very far from being settled.

THE BALANCE BETWEEN MALARIA AND THE VENEREAL DISEASES.

IF there was ever a time when malaria was of interest to practitioners in the tropics only, that time passed when Wagner-Jauregg began to use it purposefully in the treatment of late syphilis. And now it appears that the interest extends to another venereal disease. When Dr. Max Rosenburg first reached Acre he was surprised to find, he tells us,[1] that some cases of gonorrhœa in Palestine cleared up much more quickly than others. These short cases had, he found, been through a malarial infection, and the association was so constant that it could be used in forming an opinion of probable progress. Perhaps, he suggested, the high temperature of malarial pyrexia weakens the gonococcus, and it may be recalled that John Hunter a century ago noted in his Treatise on the Blood "the suspension or cure of a gonorrhœa by fevers." Spiethof, Leuzman, and Hofmann are quoted by Rosenburg as having in the last five years used artificial malarial infection in the "thoroughly successful" treatment of gonorrhœa in the adult female, and we are familiar in this country with the treatment of such infections of the uterus by the local application of heat. It would be of interest in the first instance to obtain reports from other practitioners in tropical countries. The average length of time spent in hospital by cases of military gonorrhœa is 55·7 days at home, 51·33 days in India, and in West Africa, where the malarial incidence is heaviest, only 46·7 days. These figures might be looked into more closely in the light of Rosenburg's suggestion. He goes on to ask for an explanation of the increasing prevalence in the tropics of neurosyphilis in towns, but not in the villages. He questions the validity of the reasons currently given—viz., over-dosage of salvarsan by native physicians, negative phase and lesser immunity in town dwellers; and a lowering of tone by cocaine, alcohol, and the like, in townsmen newly come from the villages. Here again he regards as significant the greater prevalence of malaria in the villages, where probably 70 per cent. of the inhabitants are infected, while in the towns the proportion falls as drainage and preventive measures advance. Should his view prove correct the future will have in store a great increase in neurosyphilis among the peoples of Asia and Africa as they drift townward.

THE annual Harveian commemoration will be held at the Royal College of Physicians of London on Friday, Oct. 18th, being St. Luke's Day, when Sir Wilmot Herringham will deliver the Oration at 4 P.M., to be followed in the evening by a "general feast" according to the instruction of William Harvey when he gave his patrimonial estate to the College.

ON Sept. 27th the eightieth birthday of the veteran physiologist, Prof. Ivan Pavlov, the Soviet Government, in honour of his work, assigned 100,000 roubles (£10,000) for the re-equipment of his laboratory in Leningrad. In thus recognising Prof. Pavlov's important services to medical science, the Government has disregarded his political views.

Summer Time, which commenced in Great Britain, Ireland, the Channel Islands, and the Isle of Man on April 21st, will cease on Sunday next, Oct. 6th, at 3 A.M., when the clock will be put back to 2 A.M. The hour 2–3 A.M. Summer time will thus be followed by the hour 2–3 A.M. Greenwich time. France and Belgium make the change at the same week-end. Thereafter travellers to the continent will not need to adjust their watches until they reach the German, Swiss, or Italian frontier.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

XLVI.

THE MICROSCOPIC EXAMINATION OF FÆCES.

PART I.*—CYTOLOGY AND ANIMAL PARASITES.

WHEN a medical practitioner seeks the aid of a pathologist in elucidating a case by examining the fæces, there are certain conditions which must be fulfilled in order that the result may be of value. It is disappointing to the pathologist, who has spent time and material on the tests applied, to have to submit a negative report couched in some such terms as the following:—

> "The specimen contained mucus, a few disintegrated pus cells and some degenerated epithelium; no protozoa or parasites were found, and no pathogenic organisms were recovered."

It is also disappointing to the clinician who receives the report; but, more important, it may be misleading if the result is negative only because the material sent for examination was unsuitable in character or arrived too long after collection, since quite a different report might have been received had the proper conditions been fulfilled. In this and the succeeding communication an endeavour will be made to show what material should be submitted for examination on different occasions, what results may be expected in the report, and what inferences may be drawn from these results, and applied to the management of the case.

Collection of Specimens.

The coöperation of clinician and pathologist is of such importance that a few words first on the selection of suitable specimens for examination are appropriate. To identify and estimate all the bacteria in a specimen of fæces, for instance, is a laborious process which may be undertaken for purposes of research or of training students in bacteriological technique, but the results would be of no practical value or application in the present state of our knowledge. There are certain routine investigations which the pathologist will make on each specimen submitted; but he has a right to expect an indication of the special features to be investigated. A short note of the clinical state and of the suspicions aroused in the mind of the medical attendant should accompany the specimen. The material sent to the laboratory should be as fresh as possible, since most of the parasitic organisms, both protozoal and bacterial, tend to die quickly when cooled to room temperature, and are readily overgrown by mere saprophytes. Further, as most of the bacteria in formed fæces are dead, it is preferable to work with a semi-solid or liquid stool. Liquid paraffin should be avoided, because the fæces containing it give messy preparations on microscopic slides, and the minute refractile oil globules are confusing when amœbæ or their cysts are being looked for. The best stool for the pathologist is the fresh liquid evacuation following a saline aperient. Recently passed mucus is the best material in which to find the entamœbæ of amœbic dysentery to be described later. Muco-pus obtained by direct vision of the lining of the bowel with a sigmoidoscope is a better material for examination, both for protozoa and pathogenic bacteria, than mucus passed with the fæces.

The fæces should be collected separately from the urine. The bladder should always be emptied before the stool is passed, in order that it may be free from urine. A chosen part of the motion should be submitted for examination, except where worms are suspected, when it is necessary to have a whole motion, so that the minute head of the tapeworm or ova may be searched for by concentration methods. In these cases the motion should be passed into a wide-mouthed jar, or pickle-jar with screw-on top. A small amount of boiled water still warm may be put into the jar, which should then be securely fastened and properly labelled as mentioned below. In other cases a portion of the semi-solid stool and any pieces of mucus or muco-pus should be sent in a small sterile and tightly corked phial. Specimen bottles with metal or glass spoon for picking up suitable material are obtainable from the laboratories where the examinations are made. The label should contain the patient's name or an appropriate identification mark, the date, the time at which the motion was passed, a note of the examination required, and the doctor's name. No time should be lost in getting the specimen to the laboratory. If it is necessary to send it by post, a little sterile normal saline solution or 1 per cent. bicarbonate of soda may be added. The postal authorities require that it should be so packed that risk of breakage in transit is reduced to a minimum, and it must be labelled distinctly as pathological material. The packet, which should be marked "*fragile, with care*," should be sent by letter post, not by parcel post.

Cytology.

Small amounts of *mucus* in the fæces are common, and are not of pathological importance. A little mucus occurs on the surface of the motion in constipation, or mixed with diarrhœic stools, and is frequent in those of patients taking aperients. This mucus is uncoloured by bile and contains no cells; it is probably from the lower bowel. Larger quantities indicate irritation of the bowel, and masses forming strings or casts occur in *mucomembranous colitis.* At times these casts are several inches or more in length; the mucus is glassy-white or grey in colour, and contains some epithelial cells. Mucus from the large intestine is usually white or uncoloured; when it arises from the small bowel it is often bile-stained. *Sloughs* or mucus containing plaques of intestinal epithelium arise from necrosis in an ulcerated area and may be found characteristically in the stools of typhoid fever patients during the third and fourth weeks.

Muco-pus, leucocytes and pus cells mixed with mucus, may have been swallowed from the nasopharyngeal or bronchial tracts; when it arises from the bowel, it indicates an ulcerative condition of the colon, dysentery, chronic ulcerative colitis, or diverticulitis. The pus cells are usually degenerated.

Fresh pus in separate masses arises from the rectum or sigmoid, and may come from a fistula-in-ano, a proctitis of simple origin (e.g., from enemas) or a tuberculous, syphilitic, or gonorrhœal proctitis, or from an abscess which has burst into the lower bowel. In females the pus may have come from the vulva or vagina, and the possibility that a little bright blood or blood-stained mucus may become added to the motion during menstruation must be remembered.

Blood.—Bright blood-clot with intact blood corpuscles comes from rectum or anus, usually from hæmorrhoids; it is found streaking the surface of the motion or forms a little pool apart from it. Blood corpuscles mixed with mucus or muco-pus indicate an ulcerative lesion of the colon; the small motions produced with straining in dysentery and the summer diarrhœa of children may consist of little else than blood-stained muco-pus. In cancer of the colon the blood is often uniformly mixed with the mucus, forming a pink jelly, whilst in cases of ulcerative colitis the blood tends to lie on the surface of the mucus in little pools. When the blood comes from higher up in the bowel or has remained longer in it, it becomes changed, and may be recognised by spectroscopic or chemical tests. The tarry stools following considerable hæmorrhage in the upper part of the alimentary tract are recognisable by the naked eye. The significance of blood in the fæces was dealt with in a previous article in this series (THE LANCET, 1928, ii., 1353), and the chemical changes of blood into acid hæmatin and hæmatoporphyrin were described. These substances are recognised with the spectroscope, and acid hæmatin in small quantities is also detectable chemically as "occult blood." The spectroscopic test is not delicate; the colour tests are very sensitive, but are given by other substances such as meat and green vegetables. With the chemical colour tests, therefore, a negative result is significant, with the spectroscope a positive is informative. With proper precautions, and when preceded for two or three days by a diet free from hæmoglobin and chlorophyll, a positive chemical test for occult blood shows that bleeding is taking place into the upper part of the alimentary tract. Search may reveal oozing gums, slight epistaxis, or blood-stained sputum, but usually the blood is coming from an ulcer, simple or malignant, in stomach or duodenum.

---

* Part II., on Bacteriology, will appear next week.

No clear inferences can be drawn from an attempt to differentiate the varieties of *epithelium* found in the stools. The casts of mucous colitis often contain some columnar epithelial cells and eosinophil leucocytes. In ulcerative colitis and dysentery degenerated columnar epithelium is found, also rounded or polygonal cells with a large, round easily seen nucleus from the deeper layers of the intestinal wall.

Parasites.

Tapeworms.—*Tænia solium* and *T. saginata* are the commonest forms, the latter occurring more frequently in these islands. The diagnosis is made by finding parts of the worm, often isolated segments, in the fæces, and the species of tapeworm is determined by the differences in structure. As the ova are not often passed free in the motions, a negative report does not exclude the presence of these worms. In the case of a third tapeworm, *Bothriocephalus*, not so common, however, the ova are abundant in the stools and a diagnosis is readily made. The procedure recommended is milk diet for a day or two, then an anthelmintic followed by a purgative. The motions should be passed into a vessel containing warm water, without straining if possible, the object being to secure the worm unbroken. The head, no bigger than a large pin's head, must be searched for carefully. If it is not found, a doubt remains as to the treatment having been effective, though the worm may have been killed and the head digested. But as the head, if left alive will grow again, treatment should be repeated in three months' time in case of doubt.

Roundworms.—Infection with *Ascaris lumbricoides* is often multiple. On finding a worm or ova in the fæces, treatment with santonin, oil of chenopodium, thymol, or calomel is carried out, and repeated later. In threadworms, *Oxyuris vermicularis*, the eggs in the rectal mucus already contain an embryo and auto-infection occurs. Anthelmintics should be used, combined with lavage of the bowel with hypertonic (20 per cent.) salt solution or 1 per cent. santonin. With these roundworms, as with *Trichuris trichiura* (*Trichocephalus dispar*), a common parasite, reinfection readily occurs through the fingers becoming contaminated by scratching and conveying the eggs to the mouth. Careful prophylaxis is necessary, by applying an antiseptic ointment (mercury or calomel) locally, and by suitable clothing to prevent contact of the fingers during restless sleep.

The *hookworm*, *Ankylostoma duodenale*, is a rare parasite in Great Britain. Its eggs are readily found and the infection calls for energetic treatment. Cases suspected of being ankylostomiasis must be notified to the Chief Inspector of Factories, Home Office, London, S.W.

Flatworms.—The ova of the liverfluke, *Distoma hepatica*, a rare infection occurring in sheep-breeding districts, and of bilharzial dysentery, *Schistosoma mansoni*, an introduced disease, may appear in the fæces. Treatment is indicated with preparations of tartar emetic by the mouth and intravenously, also in the latter disease, by bowel lavage.

Amœbæ.

Entamœba coli is a non-pathogenic inhabitant of the large intestine. In routine examination of fæces it has been found in up to 50 per cent. of patients in Europe, though in an ordinary civilian population in Great Britain it is much less common. During and immediately after the war it was more prevalent than nowadays. There may be mucus in the stools from irritation of the large bowel, but a report of muco-pus calls for further specimens of fresh stools in order that search may be made for the amœba of dysentery.

Entamœba histolytica, the amœba of dysentery, is a finding which must be taken up at once. The disease is notifiable, and calls for energetic treatment by amœbicides, emetine intravenously, tartar emetic and its derivatives, stovarsol or yatren by the mouth, or by intestinal lavage. Repeated examination may be necessary in some cases, but one positive finding by a pathologist experienced in this work is diagnostic. A report of dead or doubtful amœbæ should be followed up. The patient should take a saline aperient, and any mucus passed should be taken for examination at once, if necessary by special messenger, or preferably examined at the bedside. In a number of cases of subacute or chronic dysentery the diagnosis may thus be cleared up and appropriate treatment instituted. The amœbæ tend to occur in showers during exacerbations, and in the intervals cysts may be found in the more solid or partly formed stools. A report of *E. histolytica* cysts may be accepted in convalescents from dysentery and in the search for possible carriers, but it must be remembered that other amœbæ which are non-pathogenic have four-nucleated cysts resembling those of *E. histolytica*. The finding of such cysts is therefore not enough, and in doubtful cases it may be necessary to test their pathogenicity by infecting cats. Some of the figures showing a high incidence of dysenteric infection in England which were based upon finding these cysts, are therefore to be accepted with caution.

Infusoria.

Certain *flagellates* may be found in the stools. They are usually of no significance, but in some cases seem to set up irritation and to give rise to symptoms. *Trichomonas* may be found in patients who already have dysentery, and may sometimes itself set up a watery diarrhœa with collicky pains. Treatment by bowel lavage with ⅛ per cent. silver nitrate solution relieves. *Giardia (Lamblia) intestinale* may be pathogenic in some 10 per cent. of the cases in which it is present, giving rise to an enterocolitis, diarrhœa with mucous stools containing blood. Bismuth salicylate or salol, thymol, santonin, or stovarsol may be used by the mouth; and intestinal lavage with 1 per cent. methylene-blue or ⅛ per cent. silver nitrate solution.

A ciliate, *Balantidium coli*, more common since the war, is sometimes associated with symptoms of chronic dysentery. It can be controlled by intestinal lavage with ¼–⅛ per cent. solution of quinine; or by thymol or stovarsol by the mouth. Mention may be made of a vegetable parasite frequently reported, *Blastocystis hominis*, which is now regarded as of no pathological significance; stovarsol is said to cause it to disappear. Patients with these infusorial infections are often found to have subacidity of the gastric juice and to respond favourably when weak hydrochloric acid is given by the mouth.

Physician, Ruthin Castle.

Special Articles.

INTERNATIONAL PHYSIOLOGICAL CONGRESS.

THE MEETING AT BOSTON.

THE thirteenth International Physiological Congress met at Boston, Mass., under the presidency of Prof. W. H. HOWELL, of Johns Hopkins University, on August 10th. The American Physiological Society, with the Federation of American Societies for Experimental Biology, entertained the foreign members and their friends, and showed a lavish hospitality. The large meeting was organised with such forethought that though over 1000 members were enrolled from 42 nations, its progress was smooth in every detail, and expressions of admiration and gratitude were heard from all sides. Over 500 members attended from the Old World, and the journey afforded opportunities of forming new and cementing old friendships. Most of the British members travelled by ss. *Minnekahda*, on which boat physiologists from twenty-two countries were represented. During the ten days occupied in the voyage many contests in sport between national and international teams formed a happy prelude to the more serious contests of the scientific sessions in the Harvard Medical School.

The Progress of Physiology.

The opening meeting was held on Monday evening, August 19th, in Sanders Theatre, Memorial Hall, Cambridge, where addresses of welcome were given by Surgeon-General Hugh S. Cumming, of the United States Public Health Service, on behalf of his Government; by Lieutenant-Governor William S. Youngman, on behalf of the Commonwealth of Massachusetts; by President A. Lawrence Lowell on behalf of Harvard University; and by the President of the Congress. These were followed by an address entitled "The Progress of Physiology," by Prof. August Krogh, Director of the Zoophysiological Laboratory at the University of Copenhagen. After directing attention to the rapidity with which the science of physiology was expanding, an expanse which was largely due to an increasingly close contact with the allied and fundamental sciences, Prof. Krogh pointed out that the unwieldiness produced by this growth made it impossible for any single human being to be familiar with modern physiology in all its branches, in the sense in which the great teachers of twenty or more years ago were familiar with the physiology of their time. The splitting up of physiology into more or less separate and independent sciences was inevitable, and we were confronted with the problem of finding the right lines of cleavage. Physiology as a science had taken its origin from the necessities of practical medicine, but most of the work done in physiological laboratories had no direct relation to medicine. The line of development which Prof. Krogh advocated was the establishment in one direction of a branch of physiology more intimately in contact with practical medicine, and in the other direction a branch which was much more independent. The time had come when special chairs and laboratories should be established for the physiology of disease, morbid physiology, or experimental medicine, if that name be preferred. The leaders of such laboratories should have no regular duties connected with the treatment of patients, but they must have at their disposal a small number of beds for the temporary study of selected cases, and facilities for studying disease experimentally on animals. The other line of development advocated was the creation in the science schools and in close coöperation with the departments of zoology, of chairs and laboratories for comparative physiology, animal physiology, or zoophysiology. Prof. Krogh's criticism of much of the work done to-day was that too many experiments and observations were being made and published, and too little thought was bestowed upon them. Facts were, of course, necessary, but unless fertilised by ideas, correlated with other facts, and illuminated by thought, they were to be considered only as material for science.

Scientific communications and demonstrations were given on August 20th to 23rd, six sections running concurrently in the auditoria of the Harvard Medical School, the High School of Commerce, and the Peter Bent Brigham Hospital. The communications numbered over 450 and the demonstrations nearly 80. We may refer briefly to those which have a more immediate bearing on the problems of medicine.

New Work on the Alimentary Tract.

L. R. Dragstedt and J. C. Ellis showed that the severe alkalosis following œsophago-duodenal anastomosis with gastrostomy in dogs was unaccompanied by any signs of tetany. W. N. Boldyreff, working with fistulæ in dogs, observed a rapid fall in the red cell count following the absorption of acid from the gut. Repeated introductions of 0·5 per cent. HCl, or 1·25 per cent. lactic acid into the stomach caused in two to three weeks a drop in the erythrocytes of more than 1,000,000 per c.mm., with the appearance of pathological forms. Cessations of such introductions was accompanied by a return to a normal count in a few weeks' time. Excess of acid in the digestive tract was thus shown to be responsible for the advent of anæmia resembling an anæmia of the pernicious type. The results of interesting and important work on fat absorption were communicated by F. Verzár. It was shown that the reaction of the contents of the small intestine is such that the higher fatty acids cannot exist there in the form of soaps. The bile acids, however, combine in watery emulsion with the fatty acids, and the resulting combination dissolves clearly in water even at pH 6·5 and diffuses readily through parchment membrane. The combination is a molecular one, and an explanation is thus afforded of the absorption of the higher fatty acids under the physiological conditions obtaining in the small intestine.

The Kidney.

E. K. Marshall reported that fish such as the toad-fish and goose-fish, whose kidneys were aglomerular, secreted urine of essentially the same composition as those provided with glomerular kidneys. The aglomerular kidney differs from the glomerular one in showing a specificity (similar to that exhibited by the salivary gland) in the elimination of substances not normally present in the urine. Thus phenol red is readily excreted in concentrated form by the aglomerular kidney, while sodium carminate and glucose are not excreted. All of these substances are eliminated by the glomerular kidney. The excretory function of the tubule would appear to be of a kind similar to that exhibited by secretory glands such as the liver, pancreas, and salivary glands. Studies in the composition of glomerular urine have been extended by A. N. Richards and his colleagues, who have now shown by means of quantitative analysis that the composition of this fluid approaches so nearly to that of an ultra-filtrate of the blood plasma as to leave very little doubt that the glomerulus is the seat of a process of filtration.

Dry heat as an effective means of increasing the elimination of urea and of chloride by the skin is recommended by F. N. Allen. This form of treatment can be used in suitable nephritic cases to produce four litres or more of perspiration daily, over long periods, and without prostration. Large reductions in the blood-urea may be brought about by this means—e.g., from 180 to 60 mg. per 100 c.cm.

Cardiovascular System.

C. Heymans reported the results of experiments which were in close accord with the fundamental work of H. E. Hering, on the rôle of the sinus caroticus in the control of the general arterial pressure. By perfusion of the innervated sinus of one dog by means of another, Heymanns was able to show that the bifurcation of the common carotid artery was the seat of receptors sensitive to changes in blood pressure, and the site of origin of impulses engaged in the reflex control of cardiac rate, of the arterial blood pressure, and of the secretion of adrenalin. All the cardiac, vasomotor, and adrenalin-secretory phenomena which had generally been attributed to a direct action of changes in blood pressure on the medullary centres were shown to be of a reflex nature.

W. Raab provided evidence that a hyperexcitability of the vasomotor centre to the CO_2 tension in the blood was to be regarded as a pathogenic factor in essential hypertension. The CO_2 tension in such cases was not greater than normal, but slow deep breathing was followed by a fall in the tension of this gas and in the blood pressure. Breathing a mixture consisting of 3 per cent. carbon dioxide and 97 per cent. oxygen produced a fall in neither, from which it was concluded that the fall in blood pressure encountered before was due to the accompanying fall in the CO_2 tension in the blood. The effect is absent in hypertension associated with nephritis.

Pharmacology.

C. H. W. Lucas and V. E. Henderson reported the results of a study of the anæsthetic properties of cyclopropane. This gas produced rapid anæsthesia in cats in a concentration of 11 per cent. in oxygen. No depression of the medullary centres was observed, but a fall in blood pressure occurred when the concentration of the gas was raised to 25–30 per cent. Animals were anæsthetised on three successive days, for periods of two hours without any toxic effects being manifested.

Sodium amytal has been used by L. G. Zerfas, H. A. Shonle, E. E. Swanson, and G. H. A. Clowes as an intravenous anæsthetic in man. Like other barbituric acid derivatives, this salt undergoes hydrolysis, and ultimately decarboxylation when held in solution. It should be highly purified and its solution (10 per cent. in distilled water) accurately adjusted to an appropriate pH value, if used for producing anæsthesia in man. There is frequently a somewhat prolonged period of post-anæsthetic sleep, which in dogs could be successfully counteracted by the intramuscular injection of ephedrine and caffeine. The highly purified and accurately adjusted preparation has been used successfully for human anæsthesia in upwards of 1000 cases.

A. E. Koehler, L. Eichelberger, and A. B. Hastings reported that they had succeeded in separating from the suprarenal gland an epinephrine-free substance which was capable of elevating the basal metabolic rate and producing improvement in various clinical types of asthenia. These effects were obtained by oral administration of the extract.

Carbohydrate Metabolism.

A number of communications were read on the subject of insulin, but few had any present application to medicine. It is interesting that intrafœtal injection of commercial insulin in the goat caused a lowering of the maternal blood-sugar. In the depancreatised dog, absorption of insulin from the intestine was very materially increased by the presence of various liver products such as bile, or salt solution suspension of liver pulp.

The question of glycogen storage and combustion of carbohydrate in the absence of insulin has received attention, with some novel results. In the eviscerated rat (according to the work of the Cori's), injection of glucose causes no rise in the respiratory quotient (corr. value 0·71 throughout), and presumably no extra combustion of carbohydrate, but leads to a definite increase in the muscle glycogen. In the depancreatised dog (complete removal verified post mortem) survival without insulin has occurred for as long as three weeks. After the first few days the diabetic symptoms abate, the respiratory quotient creeps back to 0·9, the D : N ratio drops below 1, and the acetone bodies diminish markedly. If insulin is now given and then stopped the usual severe diabetic symptoms return once more. This work was reported by Soskin and Campbell, working at the Toronto laboratories.

Muscle.

The physiology of muscular exercise was the subject of nearly 30 communications. Two workers reported successful preparations of isolated involuntary muscle which behave regularly. Bozler, using the retractor pharynx of the snail, *Helix pomati*, has studied the relations of heat production and tension and found this plain muscle to differ only in the time relations of these quantities from the skeletal (voluntary) muscles of the frog. McSwiney and Robson have prepared sections of mammalian stomach muscle with vagus and sympathetic innervation, and studied the effects of stimulation of these nerves under various conditions.

Shaffer and Grünbaum have measured the excretion of lactate as a result of exercise (rowing, football, &c.), both in the urine and in the sweat, and record that in certain circumstances, notably in warm weather, the excretion is mainly through the skin. With the aid of cinematography, Fenn has analysed the movements of running men, and calculated their efficiency. 22½ per cent. of the chemical energy liberated was developed as mechanical energy. The relative values of wind-resistance, gravity, and the checking of limb movements, as sources of energy loss, could be estimated.

A neat technical advance was that of Sosnowski, who has constructed a tension recording-lever for small muscles, based on the piezo-electric properties of quartz crystals. It is claimed that tensions developed in truly isometric twitches can be measured.

The Final Days.

The closing address of the Congress was given by Prof. Léon Fredericq, President of the Second International Congress which met at Liege in 1892, his subject being "Souvenirs des premiers Congrès de Physiologie." An invitation to hold the next meeting of the Congress in Italy was accepted with acclamation.

The foreign members of the Congress were conducted to Woods Hole, where they were entertained at the Marine Biological Station, which is situated in beautiful surroundings. The party then visited New York, where they were the guests of Columbia University for a week, during which time many excursions to medical centres, research institutes, and other places of interest were made.

From New York 200 of the visitors went up the Hudson River to Albany, where they were met and conveyed by motor coach to the laboratories of the New York State Department of Health. They were made welcome by the staff, entertained to an informal supper, and taken in small parties over the laboratories. Within four hours they were travelling on to Canada, but those four hours were a memorable example of quietly efficient and kindly American hospitality. At the Niagara Falls the party halted for a day to view the Falls and the famous rapids. Prof. Best escorted the party down the Niagara River and across Lake Ontario to Toronto, where the University lent its dormitories for the accommodation of members for two days. Though one of these days was a national public holiday, the laboratories were kept open, and the delegates were able to see the work in progress. Prof. Henderson and his energetic committee entertained the party to lunch, the Prime Minister of Ontario and his Cabinet to dinner. Continuing their journey across the Lake and down the St. Lawrence River, the delegates reached Montreal, where they were received by a joint committee of the universities of Montreal and McGill. The Biological and Medical buildings of McGill were open to inspection by the delegates, as also was the Royal Victoria Hospital, and they were entertained by the city of Montreal and the province of Quebec.

The party left on the evening of Sept. 6th by the ss. *Doric*.

Opening of the Medical Schools.

SEVEN of the London medical schools inaugurated the winter session during the past week with a formal ceremony. We print below in abridged form the opening addresses delivered to the medical students of Guy's, St. George's, Middlesex, Royal Free, and Westminster Hospitals. The prize-giving at Charing Cross Hospital takes place this (Friday) afternoon.

GUY'S HOSPITAL.

SIR HUMPHRY ROLLESTON, BART., G.C.V.O., K.C.B.,
REGIUS PROFESSOR OF PHYSIC IN THE UNIVERSITY OF CAMBRIDGE.

MEDICAL SOCIETIES: THEIR ORIGIN AND VALUE.

[Sir Humphry spoke of the traditions of the Medical School of Guy's Hospital, and of the fine men and great books which had emanated from this school. Great as were its traditions, he said, Guy's did not live on its inheritance, for its *Reports*, so unobtrusively inspired by Dr. A. F. Hurst, the senior physician, were not only the oldest in London but, like vintage wines, progressively improve. In yet another direction the school of Guy's Hospital has played a pioneer part—namely, in the growth of medical societies, and thus furthering medical education and progress, general understanding, and unity. He then noted the connecting links between the Physical Society of Guy's Hospital, which flourished from 1771 to 1852, and the Medical Society of London, which was its junior by two years. The success of the Physical Society, though followed by flattering imitation, had carried with it a penalty, for the competition of younger societies killed it. Its declining years were cheered by watching the activities of its offspring—the Pupils' Physical Society, which dated from 1830. and had always been confined to students of Guy's Hospital, members of the staff being eligible as honorary members only. He continued :]

Medical Clubs.

The evolution of a full-blown medical society can easily be traced; the embryonic stage is found in medical friendships and the gregarious nature of the human man—an attractive feature more frequent and effective in early than in later life. In due course the initiative of some energetic spirit creates a medical coterie or club, and meetings for the reading and discussion of papers follow. By expansion and systematic organisation a medical club may, like the transformation of a financial syndicate into a company, give birth to a society with a more catholic membership; for example, the informal "Moorfields Club," which met in the house surgeon's room for the discussion of ophthalmological cases and problems as far back as 1866, in 1880 took steps to establish the Ophthalmological Society. Sometimes, on the other hand, the club stage is short-lived or is practically short-circuited—for example, in the formation of the Association of Physicians of Great Britain and Ireland, in which William Osler, Richard Douglas Powell, William Hale-White, Wilmot Herringham, and others were the true begetters.

Medical clubs differ from medical societies mainly in their less formal and more private character, in the more personal element, especially in the election of members, their limited membership, and usually in not possessing a library, which is such an essential asset to a medical society. To some extent this serious want may be met by a subscription to a circulating library, and in some instances the book-club element forms the basis and covers all the educational activities of a medical combination. Medical clubs very rarely publish their proceedings, but the Charaka Club of medical bibliophiles, mainly resident in New York, has brought out a number of volumes containing the papers read at its meetings. A medical club is the organised outcome of a group of men working in unison; these clubs flourished long before the word team-work became popular in connexion with those engaged in original research, but the same fundamental principle that inspires the research workers is shared by clubs or small societies designed for mutual education. Medical clubs differ much in their objectives, the prominence of the scientific and social characters varying widely. Some starting with high educational intent have become more social and postprandial, so that later the members are chosen rather for their clubbable attractions than because they are pale students. Such a lapse from the ideal of high thinking to high living is, it must be feared, more frequent in clubs made up of prosperous qualified men than in those whose members are *in statu pupillari*.

[Sir Humphry Rolleston then discussed the advantages of medical clubs in providing opportunity for the informal, private, and critical discussion of new work in a pre-publication phase, for visiting clinics at home and abroad, and in promoting friendly feeling among co-workers. A valuable and instructive, though often evaded, function of a medical club was the obligation on each member in turn to contribute a paper or demonstration; for this provided a training in the art of accurate argument and exact expression. If medical writers and speakers were compared, it was noticeable that the successful writers had more often been physicians, as the Guy's traditions proved; whereas real oratory, a rare accomplishment, seemed specially related to surgical eminence, as was so remarkably shown by the succession of William Lawrence, James Paget, William Savory, and Henry Butlin at St. Bartholomew's Hospital, and by other Presidents of the Royal College of Surgeons of England. A further debt to the early medical societies was that their publications preceded and led to the evolution of medical journals. He proceeded :]

Medical Societies.

By those who do not attend medical societies, and may perhaps regard this devotion as a youthful indiscretion, the reason confessed for their abstinence is sometimes not indolence, but a delicate disdain for self-advertisement. Modesty is indeed an admirable virtue, particularly in our rivals; but the English are somewhat prone to an excess of this fine trait, and men too diffident or hypercritical of their own work, or too much impressed by the verse expressing a desire that "mine adversary had written a book," may delay publication of their observations indefinitely so that they remain mute and inglorious, and thus may perhaps delay the progress of knowledge. The wisely modest man remains a student all his life, and recognises a medical society as a means of easily obtaining post-graduate instruction. With the passing years the habit of attending meetings wanes, and eventually is given up altogether, ostensibly on account of the increasing calls and fatigues of professional life; as a result the individual necessarily loses touch with what is going on, though with the unconscious failure of mental elasticity he may remain blissfully self-sufficient. He may excuse himself by saying that he can read it just as well and more quickly; but, even if he remembers to do so, the effect of the written word is not always the same as that of the spoken address. Further, and this is not very rare, laziness when disguised, like a wolf in sheep's clothing, under the cloak of modesty, may exert an unwholesome influence; a cynical attitude to societies in a senior tends to counteract the benefits that may be obtained from the give and take of debate; it may discourage others from speaking and sharing in the stimulating contest of wits which by a flash may create new ideas and strike out hypotheses worthy at least of being tested. At first public speaking is a nervous experience, and with many, even the best-known speakers, this is always the case; as Mr. T. P. O'Connor, the father of the House of Commons, and so an authority, has said. As the restless anxiety is felt before rather than during delivery, the intending speaker may easily be inhibited by the unkind, perhaps whispered, suggestion during a meeting that the speakers are bores; but he should estimate the significance of the snub by consideration of his critic, for it may be a case of:

> "So have I heard on Afric's burning shore
> Another lion give a grievous roar,
> And the first lion thought the last a bore."

That those prominent and keen at societies possess the faculties which make for professional eminence and success is well shown by the records of the Royal Medical Society, run by the students at Edinburgh, the Presidents of which so often reach the seats of the mighty both in the Northern Athens and in the capital of what the Scots have modestly called the southern peninsula of their country; Richard Bright, for example, was President of the Royal Medical Society before he left Edinburgh in 1813 for Cambridge, where he spent two terms before returning to Guy's. Another instance of early activity at societies as an omen of future success was seen in London about fifty years ago, when no medical meeting was said to be missed by "the three G's"—Sir James Goodhart, Sir William Gowers, and Prof. W. S. Greenfield, of Edinburgh, who reached the highest places in general medicine, neurology, and pathology respectively.

In addition to the educational advantages of merely listening to papers and following the discussion, there is the inestimable benefit, already mentioned, that writing a paper confers on the author, for it should entail a thorough review of the subject and the critical marshalling of data, ideas, and the results of his own experience. Without some stimulus of this kind, such as lecturing in a medical school or writing a book, the habit of *not* reading systematically easily gains the dominion over us, and we, though at first imperceptibly to ourselves, thus begin to drop behind in acquaintance with progressive medicine.

ST. GEORGE'S HOSPITAL.

EDMUND I. SPRIGGS, M.D., F.R.C.P.,
SENIOR PHYSICIAN, RUTHIN CASTLE.

DOCTOR AND PATIENT: FOUNDED ON 33 YEARS OF MISTAKES.

IT is perhaps not unfitting to-day to scan and set forth the relation between patient and doctor in the same way as we describe a disease in its various aspects; beginning with the history and passing on by way of ætiology, method, and complications to the prognosis and treatment.

The written history of the relation between doctor and patient shows that you are the recruits of a great army of men who have served this art, and inherit the fruit of their labours. You are more fortunate than they in many respects, of which I shall mention two. The first is that of intellectual freedom. The second respect is that as compared with even recent days, the means of controlling and arresting disease are fuller than ever before and growing daily.

Ætiology and Pathology.

As regards the *ætiology* of the relation between doctor and patient, it is, of course, the sick person who sends for the doctor. The method of selection is various. If you are chosen because you are known to be competent, live reasonably near, or have succeeded the former doctor, well and good. If you do your part there is a fair chance that the relationship will last. But if you are chosen because your patient's dinner or dancing partner told her that you were absolutely the only man for the nerves, or the gapes, or whatever it is—beware. It is a positive danger to have emotional persons going about saying Dr. So-and-so is wonderful. As soon as many people say the same it becomes the dernier cri, and this lives only a little longer than a May-fly. De la Fourchardière, in an amusing cynical book entitled "Les Médecins malgré nous," points out that once the relation is made the patient wants the doctor if there is nothing the matter to find something; if there is something the matter, he wants him to find nothing.

A *pathology* may arise in the relationship between patient and doctor on the part of either. As regards the patient, nearly every one will be a single-minded person seeking relief, ready to give you all possible help in your work, bearing illness bravely, and commanding your admiration and regard. But you will learn to recognise a few folk who are less anxious to keep to the truth than to produce a certain impression; you will also become familiar with the sublime unconscious selfishness of the neurotic; and with the imitation great who show their importance by giving trouble. The relationship is also out of order if the patient expects a sound opinion without adequate information, examination, and reflection; or to be treated without interference with harmful habits. In these days the prevalence of new ways of observing has led some patients, and some doctors, alas! to a new error—namely, that of undervaluing careful clinical method, upon which our work must always be founded, and of thinking that some test will of itself make the diagnosis. You will bend to none of these errors, but will advise what you know to be right. The difference between you and the charlatan is that you are there to do the patient good by any method, whereas the charlatan is out to sell his wares, whatever they may be. The charlatan is judged by his successes, and we by our failures. And, of course, he has plenty of successes. He benefits, like all who follow the healing art, whether qualified or not, by the simple arithmetic of illness. If everyone needs a doctor on the average ten times in his life he only dies once—that is, in nine out of ten illnesses the patients are likely to get better, provided that they are fair samples of the population. Should you become a consultant and draw your patients from your fellow-doctors, the proportion of your successes, on an arithmetical basis, will be still less, because all the easy ones will have got well, and only those who need further help will be sent.

The *method of work* is of lasting importance, and that you will be taught here. You will soon recognise that in illness there are commonly two elements—namely, the disease, and the patient's natural anxiety about it. The second element can often be put aside by a quiet assured manner on your part.

When *taking a history* you will find that patients will speak with conviction about what cannot be established—e.g., "I make such a lot of bile," or "I do not assimilate my food," "I suffer from the liver," confusing an unstated fact with an overstated interpretation. You will form the habit of keeping the symptoms and signs well separate in your mind from any interpretation or diagnosis; and will try to avoid statements about what we do not know, remembering all the time how much there is, present and active, in any case, which is hidden.

If the case is a new one, you will find it a great help to get into touch with *other doctors* who have seen and treated the patient. Doctors are colleagues, not merely rivals, and the solidarity of our profession is not only right for us, but especially good for our patients. The public does not always realise this, putting much faith in a series of so-called independent opinions, which are sometimes just unconnected guesses. From some experience of obscure and difficult problems I say that special opinions are of much more value when those giving them communicate with each other, and have knowledge which, in many cases, only the family doctor can supply.

The family doctor is the unit of all medical work. His standard has risen enormously during the last generation, and will continue to rise. He should control the case, using specialists and institutions as need arises. His is the responsibility, and this is right, for he has to live with or near his patient for their common lives. Patients who do not keep to their doctor run a considerable risk, because no one else can hold all the threads.

I believe we fail more often in simple apprehension than in the two further parts of logic. The faculty of judgment—i.e., "of arranging the individual things we meet in general notions or classes . . ." and the faculty of reasoning founded upon it are, I suggest, less often at fault; in any case neither judgment nor reasoning will avail unless founded upon a right apprehension of the available facts. If you learn how to examine properly the avoidance of certain mistakes becomes unconscious. It is like style in cricket, tennis, or golf, which requires attention to little points, details which seem irrelevant when the main object is to hit the ball hard and straight. But attention to them ends by making your play, not perfect ever, but a more skilful and better game, and a game which you enjoy more yourself. Affectations correspond to useless waggles of the bat or club. And you will avoid like poison the mental attitude of the man who holds his club up in the air after a successful shot, as if to say, "See what I have done."

Diagnosis, Prognosis, and Treatment.

The public at large has only lately begun to grasp the importance of giving time and thought to diagnosis. The attitude hitherto has been that the doctor should at the least name the disease, after a short interview, and if he does not know what the matter is, the right course is to try another doctor and get the treatment decided upon and started as soon as possible. The fruits of this attitude are sometimes astounding. For instance, if it is recommended that a young person should go abroad for six months or take a voyage round the world for health, the whole family will foregather, and if necessary subscribe to carry out what is advised. But to spend a month, or some money, in finding out what the matter is, how bad it is, and what measures do most good, strikes many people as savouring of incompetence on our part. I could recount instance after instance of people who have spent years in trying different treatments, particularly abroad, whose cases could have been cleared up by simple investigations. But this phase is abating and you will perhaps before long be faced with a converse one which I begin to meet—namely, that presented by the people who are all for diagnosis but have no time or patience to try to get well.

I have mentioned that doctors may walk into the pitfall of making a diagnosis on a particular finding either at the bedside or in the laboratory. It is necessary, particularly with unexpected findings—a lump, a large heart, fluid in the chest, a gall-stone—which puts the idea of one particular disorder in your mind, to stop and ask yourself: Is this the cause of the ill-health? Can it be anything else?—going over each symptom. When you have given time to a knotty case, and have made a diagnosis, do not be too quick to alter it. I have several times been wrong in taking a diagnosis back.

The *complications* that may arise in the relation between doctor and patient are infinite. Among the most common on the part of the doctor is anxiety; it is essential not to allow anxiety to bias judgment. If there is one place more than another where a fidgety mind is not wanted it is in the sick-room. The doctor who worries too much takes away from his own usefulness; though I suspect that he that does not worry at all is no doctor.

Doubt and anxiety will be lessened if you are able so to arrange your work that you can deal with a problem at the time. Having your facts, go into the matter fully. Keep good reference books, and read up the case without delay. To-morrow fresh puzzles will come and drive the finer points of this one out of your mind. In some cases books do not help much, for diseases are not so obliging as to confine themselves to type; and each of you will meet one day a new disease, and many times new combinations of diseases. You must then settle down and think. And such thinking will be the more fruitful the more you have heeded your anatomy and physiology, and your training in the post-mortem room and at the bedside.

On the part of the patient the worst complication is mistrust. This is only natural in the first instance, and must not be resented. By the time that you have done all in your power to help your patient it will nearly always have vanished. If not, you are justified in suggesting to him in the most friendly way that what he really wants is a doctor he can believe in. Faith is, of course, a help. De la Fourchardière, our cynic, says that is why the clergy go to Vichy and the doctors to Lourdes. Some patients fear that the doctor is trying to keep them under treatment for longer than they think necessary. There are many more whose faith wavers; not unnaturally, when they are advised to follow a prolonged tedious course involving self-denial. It is expedient to keep in mind that outside causes influence progress, for good as well as for evil. It is common to find a patient not so well and full of complaints, and learn afterwards of some personal disturbance unconnected with the disease or its treatment, such as worrying letters or the non-arrival of expected news. You will often be asked to give counsel on matters which are not strictly medical at all. If your advice may concern others, when possible see the others. Your patient's interests come first, but it is in those interests that you should not be merely an advocate of his or her views, but should guide rightly.

The *prognosis* of the relations between doctor and patient is almost uniformly good, but if an exact relation between success and gratitude is expected there will be disappointment. I remember one patient in whose case we were doubly fortunate in that a serious disease was found and means of complete relief applied successfully. He bade me farewell as follows: "Doctor, I can never thank you enough. When I came here I was done and I knew it. Now I am well again." His eyes filled with tears, he shook me by the hand, and, looking to the open windows, added, "I believe its the air." If you have learned to laugh at yourself, you will have a good deal of fun. On balance, the rewards are more than the deserts.

The *treatment* of the relation between ourselves and the sick person is clear enough if we ask ourselves two questions: (1) How should I like to be dealt with if I had this patient's disease and his mental make-up? (2) How would it do me most good to be dealt with? The ideal blend of sympathy and firmness, we can envisage, but alas! seldom attain.

It is, on paper, hard to define how much a sufferer should know about his illness. It is generally better to tell an intelligent person the truth, in as simple language as possible, avoiding technical terms and all detail which may be brooded upon later and misinterpreted. It is more skilful to put the facts so that they are not alarming than to withhold them. If a man is the subject of a serious chronic disease he often knows, at the least, that he cannot be the same again, and will be satisfied if you dwell upon how to relieve rather than upon the unlikelihood of cure. The case of cancer is sui generis, but in effect difficulty seldom arises. Above all, in your desire to answer questions frankly never go beyond what is certain. To destroy hope in the mind of any patient is inexcusable. It is also unwise, because you do not always know. We are not there to pass sentence. Remember "Guérir quelquefois, soulager souvent, consoler toujours."

Conclusion.

In all these matters you will have the advantage of learning your profession in a country in which the standard and the conduct of practice is higher than in any other; in a city the streets of which were trodden by Harvey and Sydenham, Hunter, Jenner and Young, and Lister; and at a hospital which has had more than its share of these pioneers of medicine. The physicians and surgeons at St. George's have had the reputation of being not only technicians; they have played a part in other spheres—science, literature, art, and sport. And that is one reason why they have trained so many good doctors. A doctor may suffer a little in his personality if he does nothing but work. And to keep on a level keel, you will, if you are wise, carry on our hospital tradition. Do not have all your friends doctors. Be a man among men away from the sick-room. In looking back to the devoted clinical teachers of my youth I sometimes wish that in their desire to pass on to us what was known they had left less of an impress of finality; but had rather opened our eyes to the great fields of the unknown that lay before us, and had stirred us to believe how easy it might prove to the patient observer to reveal new facts. I had the idea as a student that all the main discoveries in medicine had been made, and that new ones would come only from the exceptionally able, and that after laborious and abstruse research. It was not so, and it is not so now. A great Frenchman said nearly 300 years ago, " the sphere of our knowledge expands without ceasing, but as it increases so does the number of its points of contact with the unknown." I have only to look back upon the changes and the simplifyings that have come over medicine in my short span to know that there are those listening to these words to-day who will add to our knowledge and to the means by which we may modify and arrest disease.

MIDDLESEX HOSPITAL.

E. A. COCKAYNE, M.D., F.R.C.P.,
PHYSICIAN TO THE HOSPITAL.

LIFE'S ENDLESS CHAIN.

[Dr. Cockayne said that the subject of heredity was a branch of medicine almost completely ignored by many authors of text-books and by teachers in the medical schools. Its study afforded evidence of the close relationship of the sciences taught in the preliminary course to one another and to the theory and practice of medicine. He summarised the simple experiments made by the Abbé Gregor Mendel in 1865 which had completely altered our views on the subject of heredity, and explained the laws of inheritance of dominant and recessive characters in plants. Experimental methods of breeding had shown that the characters of animals behaved like those of plants. Dominants were transmitted direct from parent to offspring, and recessives in the presence of the corresponding dominant were handed down from generation to generation, causing no outward and visible sign of their existence in the transmitters, but appearing again unaltered whenever a mating between two impure dominants took place. Dr. Cockayne then discussed the applicability of the Mendelian law to man. He said :]

Heredity in Man.

In man no direct experiments are possible, and the small families and the slow sequence with which one generation follows another make it far more difficult to prove that in him, too, inheritance obeys the Mendelian law, but the greater the number of long and accurate pedigrees that are accumulated the more does its applicability to man become apparent. Most of these pedigrees, it is true, illustrate the inheritance of conditions more or less abnormal, those illustrating normal ones are seldom simple. For instance, the inheritance of the colour of the hair and eyes, and of pigmentation of the skin, in which segregation undoubtedly takes place, are complex cases in which more than one pair of factors are involved. One form of curly hair, however, is a good example of the complete dominance of one normal character, hair spirally coiled and oval in cross-section, over another character, hair straight and circular in cross-section, and the pedigree shows that in the marriages between a curly-haired and a straight-haired individual half the children had curly and half straight hair.

If we turn from the physiological to the border-line between the physiological and the pathological we find that the same law of inheritance prevails. In man two types of piebald are met with, and in both of them the distribution of pigmented and unpigmented areas has its exact counterpart in a breed of domesticated animal, and in both man and animals the two types of kinds of piebald pattern are dominant to the normal pigmentation. Albinism, due to partial or complete inability to form the pigment melanin in the skin, hair, eyes, and internal organs, is definitely pathological. Owing to its conspicuous appearance and its widespread though rare occurrence in many species of animals, mammals, birds, and even reptiles, it has always excited public interest. There is more than one kind of albinism, but whatever its kind and in whatever animal or race of man its mode of inheritance has been studied, it has proved to be recessive to normal pigmentation. Though rare in most races of man, amongst an isolated tribe of Indians in the Daren Peninsula of South America albinoes are numerous. The tribe does not permit the marriage of two albinoes, and its common occurrence is due to the isolation of the community and the consequent frequency of intermarriage between blood relations, who are impure dominants. In these Indians albinism is always associated with small stature and increased hairiness of the skin, and in Europeans with visual defects. I mention this because what we call a unit character is often merely the most easily recognised, but not necessarily the most important of many departures from the normal, all of which are dependent on a single factor.

Another chemical error inherited as a recessive is porphyrinuria, in which porphyrin, a red pigment easily identified by chemical tests and by spectroscopy, is excreted in the urine. Here we trespass on the domain of physics, for the chief disability of those unfortunate people, who cannot break down hæmoglobin, the red colouring matter of the blood, beyond this stage is that the porphyrin accumulates in the skin and renders it sensitive to sunlight, which blisters and destroys it. Xeroderma pigmentosum is another recessive defect, in which the skin is so affected by sunlight that cancer of the exposed skin develops at an early age, and though the nature of the defect is still unknown, its resemblance to porphyrinuria makes one suspect that it too is an inborn chemical error. If so it may prove to be the best clue to the cause of cancer. As an example of defective structure I will cite polydactylism, which is dominant in most families, and it is interesting to note that in some of the domestic animals polydactylism occurs and is inherited in the same way.

Anomalies of the ductless glands, so fascinating because of their far-reaching effects on growth and metabolism, are in some cases hereditary. Diabetes mellitus, due to a deficient secretion of insulin by the pancreas, has many different causes, but in some families a weakness of the gland is inherited and transmitted as a recessive character. Man is not the only sufferer, for in mice a strain has been met with in which the same disease is transmitted and, as in man, it is a recessive. Gigantism and acromegaly, with its strange overgrowth of the extremities, are due to over-secretion of the anterior lobe of the pituitary gland and are inherited as recessives, while the excessive and perhaps abnormal secretion of the thyroid gland, that causes exophthalmic goitre, is inherited as a dominant in some families.

One might multiply examples of inherited physiological attributes or chemical and physical defects indefinitely, but enough has been said to show in what diverse conditions Mendelian segregation of unit characters can occur.

The Chromosomes as Carriers of Mendelian Factors.

The microscope has enabled us to supplement the work of the experimental breeder by revealing to us the physical explanation of the manner in which this segregation is brought about. The student of histology sees in every artificially stained cell a deeply coloured central part, the nucleus, and in a series of sections showing the various stages of cell division he sees the nuclear material form a ribbon and then split up into a number of small pieces, the chromosomes, a number varying in different species of animals and plants, but with certain remarkable exceptions constant in any given species. In the process of formation of the germ cells, both male and female, a reduction in the number of the chromosomes takes place. Half are lost, so that a germ cell only contains half as many as any of the cells of the rest of the body. It is only by the union of a male with a female germ cell that the full complement can be reached once more. Nor is the union haphazard; each chromosome unites with its corresponding chromosome and each part of a chromosome with the corresponding part of its fellow. Long before the discovery of Mendel's paper it was believed that the nuclear material of the cell was the part which carried the qualities of one generation to the next, and recent work has consistently added strength to this conviction. If we regard the chromosomes as the carriers of the Mendelian factors that determine *inherited characters, we can understand how the* halving of the number of chromosomes in the germ cells is adapted to ensure that each germ cell shall contain one of every pair of corresponding factors, and we can also understand how the manner in which the full number is restored in the fertilised ovum ensures that one of every pair of such factors is derived from each parent.

If the cells of the body contain in a pair of corresponding chromosomes both members of a pair of factors, say A and B, the germ cells of that individual will be of two kinds, one kind having one member of the pair, A, and the other kind the other member, B. If this individual marries another of like constitution the expected combinations of their germ cells are A with A, B with A, A with B, and B with B, and each combination should occur with equal frequency, so that if A is the factor for a character dominant to B the proportions among the offspring will be one pure dominant, A A, two impure dominants, A B, and one pure recessive, B B. Thus the behaviour *of the chromosomes* is adapted to bring about the results that are actually found in experimental breeding.

So far we have dealt only with characters that are met with equally in both sexes, and the explanation given will not cover the inheritance of those met with in one sex alone. In some beetles there is a chromosome fewer in one sex than in the other. In other animals, though the number of chromosomes in the two sexes is the same, one of a corresponding pair is smaller or, as in flies, differently shaped in the cells of the one sex. Conventionally we speak of this pair of dissimilar chromosomes, which appear to be the determiners of sex, as the X and Y chromosomes, and it is found that in man the male has an X and a Y, and the female two X chromosomes in the cells of the body. Thus when the germ cells are formed all those of the female will be alike, each having an X chromosome, but those of the male will be of two kinds, one having an X chromosome like those of the female, and the other a Y chromosome. Union between a germ cell of the female and a male germ cell of the former kind containing an X chromosome will give rise to a female child, whereas union with one of the latter kind containing a Y chromosome will give rise to a male child. The X chromosome may carry factors for normal or pathological characters just like any of the ordinary chromosomes, but the Y chromosome, which as I have said may be absent altogether, seldom if ever carries any factors at all.

Female Transmitters of Abnormalities Affecting Males.

This fact gives the key to those *strange cases of* inheritance in which the male alone shows the abnormality, but has apparently healthy children, while the females, though not themselves affected, transmit it to half their male offspring. This mode of inheritance, spoken of as sex-linked, can be explained by the factor concerned lying in the X chromosome and being recessive. If an affected man marries a normal wife all his sons will be normal, because they only receive the unimportant Y chromosome from their father, but all his daughters will be capable of transmitting the condition, because the X chromosome received from the father carries the recessive factor, though the second X chromosome received from the mother carries the corresponding dominant and so makes them appear outwardly normal. Half the germ cells of one of these transmitting females must have an X chromosome carrying the dominant factor for the normal and the other half an X chromosome carrying the recessive factor for the abnormality, so that, if she marries a normal male, there will be an equal chance of either kind of germ cell uniting with a male germ cell having a Y chromosome. Thus half the male children will be normal and half will inherit the abnormality. Half the female children will be normal, and the other half will appear so, but will be transmitters of the abnormality.

In addition to normal characters, of which we know little, a number of interesting and important human *abnormalities may be inherited in this way, such as* colour blindness, hæmophilia, optic atrophy, muscular dystrophy, and deficiency of hair and teeth with absence of sweat glands, though in other families the same or similar abnormalities may be dominants carried by one of the ordinary chromosomes and so affect both sexes alike. This dissimilarity of the sex chromosomes also provides us with a scientific explanation of the popular belief that sons take after their mothers. A son receives from his mother an X chromosome bearing the factors for many characters, and all of these will affect his mental and physical traits, whether dominant or recessive, because the Y chromosome received from his father bears no corresponding member of the pairs.

I have only mentioned the simple case of a pair of corresponding characters, but there are many more complex examples. Even now we can foretell of many human characters whether they are likely to be transmitted to the offspring, and, if so, in what proportion they may be expected. If dominant they are likely to appear in the next generation and in half the children, since pure dominants are almost unknown in man, but if recessive it is most improbable that they will appear in the next generation, though they will reappear in a subsequent generation near or remote. We can give a warning that, when a recessive character has appeared in a family, marriages between blood relations and especially between first cousins are likely to result in its immediate reappearance, because many impure dominants are present in such a family and marriage between two of these will lead *to its appearance in a quarter of the children.* The adolescent insanity, dementia præcox, is an example, and the frequent intermarriages of Parsis in Bombay is the cause of its high incidence among the members of this gifted community. Amaurotic family idiocy is another example, and in this fatal disease, which is almost confined to Jews, blood relationship between the parents can be traced in the majority of cases. Two similarly afflicted people seldom marry. Deaf-mutes are the commonest exception, and since one form of deaf-mutism is inherited as a recessive some of these marriages give rise to the expected result, a family of children all of whom are deaf-mutes.

Great as the advances have been in our knowledge of the inheritance in man of characters, desirable and undesirable, during the last two decades, an almost unlimited field awaits our further progress. There may be a number of diseases which originate from an obscure but innate defect, as pernicious anæmia appears to originate from an inherited achylia gastrica. Unsuspected metabolic disorders must exist, which when discovered will shed new light on the normal chemistry of the body.

Conclusion.

The science of eugenics is in its infancy. The application of Mendelian principles to agriculture and stock raising has had far-reaching results. For instance, the output of sugar per acre in Java and of wheat in the temperate zone has been greatly increased, and the use of a sex-linked character has become the basis of a large trade in "one-day chicks" in America. But its application to the improvement of the human race has been and must for many years to come remain very limited, nor do I see how it can ever be of equal value, because the methods employed in improving a breed of domesticated animals cannot be used for man. The stamping out of undesirable characters would be easy if they were dominants, but, if they were recessives, it would be a long and perhaps impossible process, and even if the worst of all the inherited afflictions of the human race were eliminated, they would still arise again from time to time as fresh mutations.

Looking at heredity alone, can anyone say with justice that a thorough grounding in the basic sciences of chemistry, physics, botany, and zoology is a waste of time for the doctor? The same laws govern heredity in plants and in animals, vertebrate and invertebrate, even in man himself, and there can be no doubt that the parallel cases of inheritance in man and animals have a deep significance. Our understanding of this we owe to these sciences, that have revealed in part the secret of life's endless chain and shown us how, in spite of apparent gaps, it extends unbroken from one generation to generation. Surely the wider the knowledge of them a man brings to his study of medicine the more clearly he will appreciate the essential unity of nature.

ROYAL FREE HOSPITAL.

DR. JANE WALKER, J.P.

THE RETURN OF WOMEN TO MEDICINE.

Women Doctors in History.

THERE are many proofs that from the beginning of time women were quietly and efficiently tending the sick and binding up wounds. Many women doctors were in practice in ancient Greece and Rome. Œnone, the wife of Paris, had the gift of healing, and the Cornish Princess Isolde was a doctor. It has always seemed to me that there is a good deal of evidence for the book of Ecclesiastics having been written by a woman doctor. The authorship is attributed to Kohelith, a feminine word in Hebrew for a teacher. It certainly shows signs of having been written by a somewhat disillusioned person—a state of affairs not altogether inconsistent with the experience of a practitioner of the healing art of some years' standing.

In the Middle Ages learning was not widely diffused, and was not regarded as a gentleman's accomplishment, and was therefore in a certain degree left to women. Ladies of the mediæval households were both nurses and doctors. Miss Kemp Welch in "Six Mediæval Women" gives a most graphic account of the day of one of them. Many heads of nunneries studied medicine, notably St. Hildegarde, who wrote the most famous book on medicine of her time. Then there was the famous school of Salerno, where in the tenth and eleventh centuries was a fine medical school, in which women as well as men taught, wrote, and practised medicine and surgery. In the twelfth century romance, "Le Lai Des Deux Amants," there is mentioned a woman who had studied for 30 years at Salerno, and in that celebrated school had completely acquired the art of medicine. In the romance of Gwaine and Gawin, when he is wounded in his fight with a giant, he is "healed at a fair castle by two maidens who were learned in leechcraft, and they also restored to health his lion." In the Via Sacra round Athens we constantly see Greek inscriptions, such as "To Basile, the Woman Doctor," "Thecle, the Woman Doctor, lies here." In Ostia, the Rhone Valley, in Spain and Africa, many a marble slab has been found erected to women doctors by some grateful patient. Galen mentions Aspasia, from whom he copied many prescriptions, and Cleopatra, a famous gynæcologist, another of his colleagues. There must have been women doctors in Egypt for thousands of years.

There is a story told by a Latin author of the time of the Emperor Augustus, that at one time it was forbidden in Athens for a woman *or a slave* to study medicine. Whereupon a certain woman cut her hair short and dressed as a man, studied and practised medicine with such success that the women pleaded for her. Whereupon the law was repealed, and women were free to study and practise medicine. Bologna had in the eighteenth century at least seven women professors—one, the professor of mathematics, was appointed by the Pope, and another, Anna Maria delle Donne, was appointed professor of obstetrics by Napoleon Bonaparte. There were many medical women in Italy, Germany, France, England, Spain, and Poland, who practised or wrote medical works before the revival of the nineteenth century, but after the fifteenth century the number of women practising medicine became fewer, and finally almost disappeared. In Elizabeth's time, Anne Cooke, who became Lady Bacon, and her sister Mildred, Lord Burghley's second wife, were both described as skilful in surgery and distillation of waters.

In the seventeenth century Margaret, the celebrated Duchess of Newcastle, was taught physic and chemistry. During the Stuart period the sense of public duty, so noticeable in the learned ladies of Tudor times, found its chief expression in the study of medicine.

There is scarcely a description of the upbringing of girls at this time which omits all reference to the study of physics. At home the mother instructed the daughter, but this was not the only means of obtaining information. Women doctors took apprentices. We read in Mrs. Elizabeth Walker's biography that she was very competent both in "physic and chyrurgery." Her medicine store contained at her death a good store of vomits, purges, sudorificks, cordials, pectorals, almost all kinds of syrups, and strong and simple distilled waters. Some women doctors had a fashionable reputation. John Evelyn supped in the City with a gentlewoman called Everard that was a very great Chymist, and obscure country villages had their female practitioners.

When medicine became more of a science, and less of a mystic empirical art, the men of science declared that women were incapable of learning it, and gave them no chance of proving whether they were capable or not. At the same time the old prejudice as to the mental inferiority of women was helped by the new prejudice that every woman possessed of unusual skill was a witch, and deserved to be cruelly done to death. Naturally they ceased to practise medicine. In France it took 300 years of struggle to exclude women from the profession. In Henry VIII.'s reign a law was passed which prevented women from practising medicine unless they were approved by a bishop, who should call unto him four physicians and four surgeons. Apparently no women were examined and approved, but still some of them continued to heal people without payment. The passing of the Medical Act of 1858, though a great advance in many ways, made it impossible for women to practise medicine unless and until a university or corporate body with power to examine them would do so and grant them degrees.

Famous Women and Famous Men.

In our own times the onslaught on the closed and barred gates of the citadel of medicine began with a thirst for knowledge, when women demanded higher education for themselves.

Among the pioneers in the women's medical profession Dr. Elizabeth Blackwell, Dr. Elizabeth Garrett Anderson, and Dr. Sophia Jex-Blake are outstanding. Elizabeth Blackwell's name was entered on the British Register in 1859. The other two first met at a lecture given by Dr. Blackwell in London, and from this meeting was born in them the determination not only to study and practise medicine, but to make this career available to others. After many difficulties they achieved their own medical education and then, with the help of Mrs. Thorne, managed to infuse others with their spirit and to secure the foundation of the London School of Medicine for Women. Some men were sufficiently enlightened and in advance of their times to see the justice of allowing women to carry on whatever work they felt they could do. In the very early days nearly 200 men doctors had signed a petition in favour of women in medicine. Sir James Paget was one of them, although he did not quite approve of women entering the medical profession.

Sir James Stansfeld's claim to enter the army of famous men as far as we are concerned is that he was the most active agent in getting the Royal Free open to us for practical training through his influence with Mr. Hopgood, chairman of the board of management of the hospital. Later on in the same year the London University agreed to admit women to medical examination and degree. Another great man was Dr. King Chambers, who after urging women to get teaching somehow and then boldly to practise as unregistered practitioners, being ready to submit to examination when called upon, joined in helping to found our school.

It was Dr. F. A. Anstie who definitely promised to become a lecturer if the women would get a school of their own fit for first-class theoretical courses. He believed the school would get teachers from other schools if that were done, and that then, with that evidence of sincerity and energy in work, some hospital or hospitals would give way and grant facilities for clinical teaching and experience. In every move he made or suggested he was right and far-seeing. He held the office of dean for only three months, during which all the arrangements were made for starting the classes in October, 1874, but he died of blood poisoning on Sept. 12th of that year. He was succeeded by Mr. Norton from St. Mary's Hospital, who occupied this post until 1883 and he was also lecturer on anatomy. It will be interesting to students who are entering for the first time to know that it was long before he made a real success of his profession. His total earnings for the first seven years of practice are said to have amounted to two guineas, and yet he lived to ride every morning on a favourite white horse and to own a villa on the Thames as well as his house in London.

A man great in many directions was Dr. William Allen Sturge, who was appointed physician and pathologist to the Royal Free Hospital, when the hospital decided to accept women as students in 1877. He was a brilliant lecturer and a warm supporter of women's medical education. He married Dr. Emily Bovell and they started practice together in Wimpole-street; but Dr. Sturge, however, was too delicate for the severe work of a London practice and they moved to Nice. She had to contend there also against the prejudices which prevailed at that time against medical women, and indeed, even now has not entirely disappeared. Disappointed and ill and saddened, she broke down again, and died in 1885.

Dr. Buchanan Baxter was a very remarkable person. He did not begin to study medicine until he was 30, did not practise till he was 40, and he died at 50. He was physician to the Royal Free Hospital only from 1881 to 1884, but he left an ever-abiding memory and devotion behind him. Mr. Stanley Boyd became lecturer on anatomy with Mr. Norton in 1882, and succeeded him in 1883. His close connexion with the school and all its doings kept up till the time of his death in 1910. There are innumerable famous men and women, both living and who are now gone, who have really gone through a very great deal to enable the present-day young woman and student to find herself where she is. They have indeed laboured that she may enter into her labours with peace and quietness.

The Entering Students.

A few words to the entering students I think is always regarded as an essential part of this address, and a good deal of space has been given in many previous addresses to things like your food, and your clothes, your recreation, and games. I am sure the food you require is that which you like to have, and as for your dress, I regard the modern girl as well and sensibly dressed as it is possible for her to be. The only thing I feel inclined to say to you on this point is, do not let anyone persuade you to wear your skirts longer than you do at present. They are both beautiful, graceful, and really useful, as well as being economical. It is now quite an ordinary thing to study medicine, and very rarely do women doctors not find plenty of work to do. But in spite of the ordinary young woman, as the ordinary young man, taking up the profession of medicine women doctors have still to be a bit better than men of the same standing. They must be equipped, not only with the best theoretical knowledge, but with infinite patience, forbearance, business ability, tact, good health, energy, and courage. They must familiarise themselves with political, economic, and social conditions. At the same time, do not be discouraged if you make mistakes—everyone makes bad mistakes—and they learn far more from them than from all their successes. At the same time, if you start in general practice, as I hope a very large proportion of you will do, that you will probably lead a rather solitary life in a town where there are 20 men doctors to one woman, and that any mistake you make will be handed round the town and be magnified 20 times more than any one of their blunders.

Women must be loyal to each other. It is a great thing for you at this school that so many of your professors and teachers are at the top. It is one of the disadvantages of the co-education schools that most of the people at the top are men. This brings on an undue state of humility with women students, and makes them unable to visualise themselves at the top, at which we ought all to aim. Disloyalty to women takes place where women compete with women for the favours of men, as in love, and where women compete with men for the favours of men, as in our profession. The French say it is men who make women dislike one another, and there is a Latin author who says, "Nothing is more unbearable than a woman with a full purse," and especially is this so when she has made it full by her own exertions. Do not let your loyalty to anyone be mere servility. It is no good truckling to anybody. Never be afraid of what people think of you. Do what you honestly think is right and leave it. Realise that you are human beings first, and women afterwards. Only as you do this will you attain that perfect freedom which we should all have as our aim, both for ourselves and for others.

WESTMINSTER HOSPITAL.

F. N. KAY MENZIES, M.D., F.R.C.P.,
MEDICAL OFFICER OF HEALTH AND SCHOOL MEDICAL OFFICER FOR THE COUNTY OF LONDON.

THE LOCAL GOVERNMENT ACT, 1929.

SIX months from to-day (Oct. 1st) an Act of Parliament will come into full operation known as the Local Government Act, 1929. This Act may truly be described as one of the greatest and most revolutionary advances in public health and social administration which has occurred in this country for over 100 years.

The portion of the Act to which I refer may be quite briefly summarised as follows: The Act transfers to the London County Council, on and after April 1st, 1930, the whole of the medical services, indoor and outdoor, of the poor-law guardians of London, and the whole of the powers and duties of the Metropolitan Asylums Board.

That means in effect transferring to one public authority—viz., the L.C.C.—over 100 public hospitals and institutions for the treatment of the sick, containing about 50,000 beds. Now, inasmuch as the L.C.C.

already provides over 20,000 beds for mental cases in their mental hospitals, and a large number of other beds in a variety of hospitals for various diseases, it will mean that the L.C.C. will have under its own direction and control no less than 75,000 beds, dealing with every variety of disease. That is, about five times as many hospital beds under one public authority as there are to-day in all the voluntary hospitals in the whole of London.

[Dr. Menzies traced the evolution of public health administration in this country during the last hundred years and pointed out that it had proceeded along certain lines of definite logical sequence. There was first communal health, or environmental hygiene, as exemplified by housing, water-supply, sewage and refuse disposal, infectious diseases, and so forth, and then came personal or individual health, as exemplified by the tuberculous patient, the V.D. patient, the orthopædic patient, maternity and child welfare, and the midwife. Moreover, the poor-law authorities of this country had, from the time of Elizabeth, been concerned with the relief of destitution, either in the form of cash or kind, or by means of institutions—viz., workhouses. Poor-law guardians relieve destitution—they have no choice. If a sick poor person could not obtain the medical attention he or she required elsewhere, the poor-law guardians had to provide it—even if the poor-law hospital or infirmary was overcrowded. Voluntary hospitals, on the other hand, made their own selection of cases, and were under no legal obligation to take in any particular patients. He continued :]

The great bulk of hospital treatment of the sick in this country is provided by poor-law guardians out of rates, and by the public health authorities out of rates and taxes, and not by voluntary hospitals—e.g., 350,000 beds in England and Wales, compared to 50,000 in voluntary hospitals—and in London 75,000, compared to 14,000. Not only all these hospital beds are provided and paid for out of rates and taxes, but they are in existence now, and have been for many years past. The London County Council, therefore, is not going, as some people seem to think, to create an entirely new public hospital service in connexion with its duties under the Local Government Act, 1929, but is simply taking over and centralising under one authority what is actually a going concern to-day, and humbly hoping to improve it.

Public opinion has long rebelled against the principle that a person who is technically "destitute," owing to sickness, must, if he is treated by the poor-law guardians, be regarded as a "pauper," and public opinion has prevailed at last. The agitation in favour of transferring the duties of the poor-law guardians with regard to the treatment of the sick to the public health authorities has been going on for over 25 years, and has only now, in the Local Government Act, 1929, been satisfied. The great change which will shortly come about in London and elsewhere is based, not on any mere sentimental whim or political prejudice, but upon the recognition of a principle that if a person is sick and is in need of treatment, and for any reasons he or she is unable to obtain it, then it is the business of the health authority to provide it.

The Effect on the Voluntary Hospitals.

There is a great fear, and a very natural one, that in some way or another the voluntary hospitals of this country will be adversely affected. Those who say that their days are numbered base this fear mainly on the belief that voluntary sources of income will gradually disappear, with the result that in time they will either be bound to receive large financial grants from the public health authority or close their doors. There are others who believe wholeheartedly in the continued generosity and financial support from the charitable public, with possibly some modification or adaptation to meet new conditions—such as massed weekly contributions from working men and women, or some organised form of voluntary sickness insurance, or the conversion of a larger proportion of beds into pay-beds on a higher scale of fees, or a combination of all these and others I have not mentioned.

There is very little, if any, practical experience to help us in making any forecast or coming to any decision on this extremely difficult and perplexing problem. I know of no reason, at all events in London, why there should be anything else but cordial and harmonious coöperation for the common purpose of promoting the welfare of the sick of this great metropolis, and, moreover, if such coöperation were properly established in London, it would be a great example to the rest of the country, and would have far-reaching beneficial reactions throughout England and Wales. For over 20 years past the policy of the London County Council has been cordial coöperation with the voluntary hospitals of London ; the Council has continuously and consistently sought the assistance of voluntary hospitals; at the present moment about £150,000 per annum is spent by the Council in financial grants to voluntary hospitals and voluntary committees in payment for work done on behalf of the Council.

Conclusion.

The London County Council and the members of their medical staff will be called upon very shortly to undertake the greatest responsibility which any single public authority in this world has ever been asked to shoulder. *The administration, efficiently* and economically, of a hospital organisation containing over 75,000 beds is a stupendous task.

If this task is going to be carried out successfully we shall need the cordial sympathy and whole-hearted support of all those who are genuinely interested in the care of the sick. The prestige and good name, not only of the Council, but of London is at stake. All right-thinking persons in every section of the community desire to make our hospital service, both public and voluntary, even more efficient than it is. Therefore, this is emphatically not a time for dissension between the public and voluntary hospital services. It is emphatically a time for coöperation to the best of our ability for a common purpose.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

THE following appointments are notified : Surg. Comdrs. R. A. Brown and J. F. Ainley to *Egmont*, for R.N. Hospital, Malta ; Surg. Lt. J. G. Currie to *Tamar*, for R.N. Base, Singapore.

ROYAL ARMY MEDICAL CORPS.

Maj. M. B. H. Ritchie to be Lt.-Col., vice Lt.-Col. and Bt. Col. W. R. P. Goodwin.

Maj. T. H. Twigg is secd. for serv. under the Colonial Office.

J. M. Gibson to be Lt. (on prob.).

ARMY DENTAL CORPS.

Capt. A. R. Inglis to be Maj.

G. A. Ballantyne, late Capt., A.D. Corps, to be Capt.

INDIAN MEDICAL SERVICE.

Majs. to be Lt.-Cols. : R. F. D. MacGregor, A. L. Sheppard, P. K. Gilroy, J. A. A. Kernahan, M. L. C. Irvine, E. W. O'G. Kirwan, and G. L. Duncan.

Capts. to be Majs. : Shankar Lal Patney, Dwijendra Nath Bhaduri, Raghunath Ganesh Dani, P. F. A. Grant, and Coimbatore Subramania Venkataramanan.

The undermentioned appointments are made : To be Capts. (on prob.) : Capts. R. L. Frost and K. S. Fitch. To be Lts. (on prob.) : W. McAdam, W. McCoach, G. G. M. Davis, D. H. Waldron, E. P. N. M. Early, and E. B. Eedle. To be Temp. Lts. : Khurshed Jilani.

Lt.-Col. M. L. C. Irvine retires.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

Reorganisation of Health Services.

THE Department of Health for Scotland has lost no time in issuing directions to the local authorities for preparing their schemes of reorganisation. In a circular dated Sept. 10th the Department analyses the leading powers of the new Act, and promises special circulars later on infectious diseases (including tuberculosis) and venereal disease, milk-supply, unsound food, food and drugs, maternity service, and child welfare and school health administration Meanwhile, in concert with the Scottish Office, it gives general directions for applying the Act in the localities.

The new Act will not come into operation until May 16th of next year, but the circulars are intended to enable local authorities to master the difficulties of detail that are certain to develop between the town councils and the other authorities within the cities, and between the county councils and the burghs within the counties. Only a special study of the duties of these bodies could make intelligible the amount of detail to be adjusted and readjusted. It is enough to say that the health circular emphasises the elements involved in a unifying of the health service under the single authority. One of the chief difficulties will be the incorporating of the school health services with the others. The circular says:—

> "The relationship between the public health committee and the education committee, and the division of functions between those committees, will have to be worked out in detail in the light of experience. Meantime, it should be kept in view that the school medical service as a health service should be definitely linked up with the other health services. Such an arrangement will facilitate the development of the service for the pre-school child. On the other hand, the full benefit of a scheme of medical inspection will not be secured unless the school health service is closely associated with education in order that the general principles of hygiene may be applied to the scheme of education, and that in particular all questions affecting individual children may be clearly considered from the educational point of view. The medical officer of health or a special medical officer on his staff must keep in close touch with the development of all schemes of education, and exercise his influence in moving policies in such a way as to secure for the child the best possible conditions for his proper physical and mental development."

Probably the major problem will be the reorganisation of the hospital facilities. The policy of the Department has been expressed in the Mackenzie Committee's Report—namely, complete coöperation between all the hospitals within the district as well as with the teaching medical schools.

> "The ultimate object of any hospital policy," says the circular, "must be to bring a complete and efficient hospital service within the reach of all. The Mackenzie Committee considered that this could best be obtained by the full development of both voluntary and public authority services working in co-operation. With this view the Department are in full agreement, and they have noted with pleasure that since the publication of the Mackenzie Committee Report there has been increasing readiness on the part of public authorities and voluntary hospitals to enter into co-operative arrangements. Hitherto the duties of local authorities in the provision of hospital beds under maternity service and child welfare schemes, and schemes for the treatment of venereal diseases, have in many cases been discharged through the agency of voluntary hospitals. Similarly, voluntary institutions provide a good deal of accommodation for tuberculous patients, more especially for non-pulmonary cases. It is probable that in the less populous areas this method may continue to be the most effective way of meeting the need for the provision of additional accommodation, and its desirability is indicated where such an arrangement facilitates the provision of one effective hospital unit, and obviates the building of a number of small units.
>
> "In other areas it may be found expedient that the local authority should itself provide the accommodation, but whichever course is followed, the essential point is that there should be an agreed policy between the local authorities and the managers of the voluntary hospitals.
>
> "Section 27 provides safeguards to ensure that local authorities take reasonable steps to secure co-operation with the voluntary hospitals and the medical schools serving the area of the authority. It is of the first importance that the development of hospital services in every area should be a matter of agreement between the public authorities and the voluntary hospitals. The machinery for securing contact between the public authorities and the managers of voluntary hospitals has been provided by the setting up of regional committees by the voluntary hospitals. A regional committee has been established for each of the four areas centring round the medical schools of the four universities, and a fifth regional committee has been established for the northern area. The machinery for co-ordination has been completed by the appointment of a Central Liaison Committee representing the voluntary hospitals, which will act in liaison between the five regional committees and the Department. The Department consider that the councils will be well advised to make touch with the appropriate regional committee at the earliest possible moment."

The principle of unification extends to diagnostic and treatment clinics as well as to hospitals. For diseases other than infectious, powers of recovery of the costs of treatment are conferred by the Act, but the Act does not require a local authority to make recovery. The view of the Department is, as in the case of maternity service and child welfare, that recovery should not be enforced to an extent that will discourage persons in need of treatment from obtaining it.

Transfer of Poor-law Functions.

Two circulars, dated Sept. 23rd, have also been issued detailing the necessary duties to be transferred from the poor-law to the local authority.

The transfer of the duties performed under the poor-law is even more difficult than the consolidation of health services, and there the question of settlement emerges. The local authorities may provide that any assistance that may be granted either under the Poor-law Acts or under any other Act, shall in future be wholly provided under such other Act, and thus be taken out of the category of poor relief. The town clerk of Edinburgh, however, in an elaborate report submitted to the town council, points out that if the assistance is given under the poor-law, the amount of the assistance given can be recovered from the authorities of other areas, where under the law of settlement liability attaches to these other authorities. But no such recovery can be made where the assistance is not given under the poor-law. Accordingly, if the conditions under which assistance is given in Edinburgh are regarded as more favourable to the recipients than in other areas in Scotland, the tendency may be to attract people to Edinburgh who would not otherwise come, and thus impose upon the Edinburgh ratepayers the burden of assisting persons who do not belong to the city.

In his report the town clerk makes suggestions for a highly specialised system of committees. He says:—

> "Many members of local authorities and other persons interested in public administration have recognised that, through the force of circumstances and the pressure of business the Town Council of the future must become more and more a deliberative and less and less an administrative body. The Town Council on this view will, in short, become something of the nature of a Parliament—the local parliament for the City of Edinburgh. It will then concern itself mainly with policy and the general direction of affairs, and it will be left, as far as possible, to Committees to carry that policy into effect and to attend to all the details of administration. Where the duties are so many and so varied it is apparent that each councillor cannot be expected to keep in close touch with every subject which comes before the Council. Individual members of Council, while having a general cognisance of the direction of the policy of each department, will require to specialise in particular branches of municipal administration. It would seem that a system of devolution of duties would greatly assist this process of specialising."

From all these documents it begins to be clear that a genuine revolution in administration has now begun. One main result will be a reduction in the personnel of the administrative bodies and an increase in the responsibility of the chief officials.

The New Chancellor of Glasgow University.

Sir Donald Macalister, retiring Principal of the University of Glasgow and President of the General Medical Council, is to be nominated as Chancellor of the University. By Sir Donald's friends all over the world this nomination will be received with the warmest good feeling. Only those who are familiar with the administration and growth of the Scottish universities can even approximately estimate the value of his services to Glasgow. It is not only that he has succeeded in establishing a large number of chairs and lectureships but that he has done so, all along, in the light of universal culture. It would be difficult to name from any country a man of greater accomplishment, and after a long and strenuous life he comes into this honour because of his sheer fitness for the post.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

Abdominal Tenderness and Unnecessary Operations.

FOR some time Dr. J. B. Carnett, professor of surgery in the University of Pennsylvania, has denied [1] the validity of the doctrine, enunciated by Head and Mackenzie, that cutaneous areas of hyperæsthesia are related to visceral disease. The disease known as chronic appendicitis he declares to be non-existent, saying that nobody has ever described a syndrome characteristic of chronic appendicitis which he is not able to demonstrate in dozens of cases that have had the appendix removed. Parietal tenderness is, he says, due to parietal neuralgia, and is the cause of hundreds of unnecessary operations. Where it is found in the right upper quadrant the gall-bladder is attacked, when in the right lower quadrant the appendix or the tubes or the ovary. Patients are seen showing as many as five abdominal scars who still complain of the original tenderness and pain. It is true that very many of these patients are of a neurotic type, but their suffering is none the less real.

To distinguish parietal tenderness from that due to genuine deep-seated disease Dr. Carnett has developed a technique of his own. The patient's abdomen is first palpated in the ordinary way and the tender area or areas are observed, together with the degree of pressure required to cause pain. The patient is then asked to blow up the abdomen. When the muscles are thus made voluntarily rigid, tenderness will not be elicited in deep-seated disease, because the damaged area will be protected; parietal tenderness, on the other hand, will be as readily elicited as before. Another test is to seize a portion of the skin and fat between the thumb and forefinger and apply increasing pressure. The full force of this squeeze may cause discomfort but will not evoke pain in the absence of a neuralgia. In the neuralgic subjects, however, a very gentle squeeze will often suffice to make them wince. The areas of tenderness will be found to correspond to the peripheral distribution of nerves. If the lower quadrant is affected tenderness will also be found for the breadth of two fingers below Poupart's ligament (ilio-inguinal nerve) and also over an area of the buttock above a line joining the trochanters (ilio-hypogastric nerve). This anatomical distribution of tenderness assists the differential diagnosis and also excludes malingering. The neuralgia may result from toxæmias. from herpes zoster, and from injuries or deformiti[illegible] lf the spine. Lordosis is a common cause b[illegible]here are while arthritis is common in later life. [illegible]ontinued

B~the charitable[illegible]rivileged to attend one of Dr. [illegible]odification or adapta[illegible]st of the patients had already such as massed weekly lost the appendix without any lasting relief from the symptoms for which they had suffered operation. Although Dr. Carnett had not seen them previously he was able to demonstrate his signs with complete success, the delimitation of "pinch tenderness" by areas of nerve distribution being quite striking. One could not help remarking that under the conditions of the clinic there was a possibility that suggestion might affect the patient's response, but this can, of course, be ruled out in private practice. Dr. Carnett's teaching is certainly heretical, but there are a few surgeons and a number of internists who believe that it contains an important measure of truth and that a considerable number of appendices are removed without justification. Whether peripheral or intercostal neuralgia is as common as Dr. Carnett believes, only the application of his tests by independent observers can show.

Tick Paralysis.

The common tick of the Rocky Mountains, *Dermacentor andersoni*, may be the carrier of several kinds of illness. There is the true Rocky Mountain spotted fever which closely resembles exanthematic typhus. There is a tick fever without exanthem, with apparently a shorter incubation period and a much lower fatality, which may or may not be a variety of the same disease. There is the quite distinct infection with *B. tularense*, and finally there is tick paralysis. A case of this rather uncommon affliction has lately been reported.[2] When first seen the patient, a boy of 10 years, had a temperature of 100° F. with rapid pulse and weakness. He was unable to walk, and when he tried to stand he had to be supported stiff-legged against the bed. Abdominal and patellar reflexes were absent. On the next day he was drowsy, unable to lift either leg from the bed or to raise his head. There was a partial ptosis of the left upper eyelid and diplopia. The temperature was subnormal. The boy was then bathed and a tick found on his back was removed. Within three hours he desired to get out of bed and did in fact get out of bed. The next day he appeared to be completely recovered. The rapidity of recovery from these severe symptoms, when once the tick is removed, appears to be typical of this particular tick disease.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

Prof. Noorden's New Clinic.

DURING the past ten years or so the Municipal Board of Health has been systematically working to secure better health for Vienna and better treatment of the sick. Tuberculosis has been attacked at its very roots; slums have been destroyed, and over 40,000 light and airy dwellings have been handed over to the working-class population; a hospital for rheumatic diseases, with 350 beds, is in course of construction; three children's hospitals have been added to the city's institutions, and now Prof. Karl Noorden, who from 1906 to 1913 conducted the first medical clinic of Vienna University, has consented to take over a model department in the municipal hospital devoted solely to the study and treatment of metabolic disorders. He will have 50 beds and a staff of selected specialists at his disposal, and will advise the authorities on dietetic problems. His clinic will have a special kitchen where physicians, nurses, and cooks will get suitable instruction. It should be distinctly understood that Noorden's return to Vienna, which he left some years ago for personal reasons, is not due to his appointment to a university chair; his age, which is 70, would prevent such a call. The Municipal Board of Health, however, has thought it a considerable gain to have the coöperation of so important an authority, whilst Noorden, on his side, gets an unlimited opportunity for further research, his position being quite exceptional. He will take up his work here early next year, and it is expected that his "school" for specialists will be a centre of attraction to medical men—and patients—from all parts of the world.

Infectious Disease in Austria.

A report by the Federal Board of Health shows that not a single case of typhus, small-pox, or cholera occurred in June–July. In the same period ten cases of encephalitis lethargica were noted and three cases of acute anterior poliomyelitis; other notifications of fresh cases being scarlet fever, 073 (3 deaths); diphtheria, 587 (12 deaths); typhoid fever, 155 (13 deaths); paratyphoid, 112 (7 deaths); epidemic encephalitis, 5 (1 death); puerperal fever, 20 (6 deaths); trachoma, 49; varicella, 351 (no deaths); and bites by suspected animals, 24 (no deaths). On the whole the health of the population was conspicuously good up till end of July, but since then there has been an epidemic of sore-throat both in Vienna and in many of the health resorts, in spite of the glorious weather we have enjoyed until quite lately. Ordinary colds, followed by otitis media and nasal sinusitis, are somewhat common at present in Vienna, perhaps because of the sudden exchange of an abnormally long heat-wave for cold autumn weather. Some observers think that the large incidence of respiratory infections is traceable to contamination of the water of swimming baths and ponds, which are frequented by enormous crowds of bathers. They hold that chlorine disinfection is not done as thoroughly as is desirable in hot weather.

Immunity to Syphilis.

At a recent meeting of the Vienna Society for Microbiology Dr. Prigge, of Frankfort, said that natural immunity to syphilis consists only in protection against the development of a primary lesion, and does not prevent invasion of the body by spirochætes. In animals apparently resistant to syphilis we see a general infection without symptoms, secondary and tertiary symptoms being sometimes visible much later. Kolle and his collaborators have shown in extensive investigations, lasting many years, that the immunity acquired by the rabbit through infection is not a true immunity. It is not transmissible passively, and the hope of obtaining a serum against syphilis is unjustified. Immunity takes 90 days to develop in the rabbit. The animals are then protected against the manifest effect of a reinfection with a homologous spirochæte; human beings, on the other hand, acquire immunity to heterologous organisms. In case of reinfection the resistance of the "immune" individual prevents the formation of a primary lesion (the chancre-immunity of Kolle), but allows the propagation and multiplication of spirochætes in the body, so that under certain favourable conditions aortitis, tabes, and general paralysis may be induced. Further research, said Dr. Prigge, is still badly wanted to clear up the problem of immunity against syphilitic infection.

The Symptoms of Rabies in Man.

Prof. Schweinburg, the director of the Lyssa Institute of Vienna, not long ago, at the invitation of the Vienna Medical College, gave an account of the chief symptoms of lyssa (rabies) encountered in persons bitten by infected animals. Apart from prodromal local pains at the site of the lesion, mental and nervous supersensitiveness, he said, appear early. The histological picture is that of a diffuse non-purulent encephalomyelitis, with infiltration round vessels and ganglia, the medulla oblongata being chiefly affected. Stimulation of any of the sense organs produces excessive responses. Breathing is difficult and oppressed, the muscles of the pharynx and œsophagus are over-irritable, and go into spasm with every effort of swallowing (hydrophobia). Later on the slightest tactile or sensory irritation (noise, light) produce twitching and spasms of the muscles of deglutition. These symptoms are never absent, and another constant symptom is ærophobia—i.e., spasms are elicited by a light blowing on the patient's face or by a draught of warm or cold air. On the second or third day very marked salivation appears; the quantities of saliva produced are so large that they are spread abroad by breathing or speaking. The temperature, at first normal, runs up toward the end to a very high level; in the blood count mononucleosis often develops, whilst the eosinophils and basophils disappear. After three days the excessive irritability of the central nervous system is exhausted, and the paralytic stage sets in. This is often rapidly followed by death, but sometimes the condition appears to improve, because the spasms disappear and the patients may take food, whilst supersensitiveness is absent. Paralysis of the heart, however, soon ends the patient's life. The paralytic type of lyssa, with absence of the spasmodic stage, is very rare in man—being perhaps relatively common in children—and a recurrent type is still rarer. No treatment is of any avail for manifest hydrophobia, for hitherto all inoculations or vaccinations have proved useless, and the same applies to various forms of chemical, biological, and internal medication. The only effective measure is preventive vaccination, lasting 13 days, and the mortality of such vaccination is now nil.

Obituary.

ERNEST EDWARD GLYNN, M.D. CAMB., F.R.C.P. LOND.,

LATE PROFESSOR OF PATHOLOGY, UNIVERSITY OF LIVERPOOL.

Ernest Edward Glynn died of diabetic coma on Sept. 22nd at Nerquis, near Mold, where he had been living in retirement since his health broke down in the autumn of 1927. He was born in 1878, the eldest son of Emeritus Professor T. R. Glynn, of Tremeirchion, who was for so many years professor of medicine in the University of Liverpool. Educated at Liverpool and at Clare College, Cambridge, Glynn qualified in 1898 and took his M.B. in 1901 and M.D. in 1908. In 1904 he became a Member of the Royal College of Physicians of London and was elected to the Fellowship in 1918. He intended originally to be a clinician and became an assistant physician to the Liverpool Royal Infirmary, acting at the same time as an assistant in the pathological department under Rupert Boyce. He proved such an efficient substitute during his chief's absences abroad, and when he was laid aside by illness, that in 1912 he succeeded him as Holt professor of pathology, and nominally gave up his clinical associations, though he was to the end at heart as much a medical man as an academic pathologist. Glynn was brought up in the broad outlook which includes morbid anatomy, bacteriology, and experimental pathology, and seeks to weave out of them a harmonious knowledge of disease. His students reaped the benefit to a singular degree and, as anyone knows who has acted as external examiner in Liverpool in recent years, they reached a standard of

PROF. GLYNN.

[Photo by Medrington, Liverpool

interest and knowledge which is quite exceptional. His methods may have been dogmatic; they gave at any rate a clear picture, and after all it is better for a student to have a crystallised scheme which is only partly right than an amorphous mass of muddy uncertainty. His influence and inspiration extended too beyond the undergraduate days of his men and, especially in the last few years, he had been remarkably successful in activating the younger graduates of his school.

Ernest Glynn took a keen interest in the growth of the Pathological Society of Great Britain and Ireland and was its honorary treasurer for many years. He attended its meetings regularly, and many of his contributions to pathological research took the form of communications to this society. He often joined in discussions at the Liverpool Medical Institution and showed there how closely he followed clinical medical progress. His catholic interests are shown also in the variety of topics which he advanced by his original work. To him is chiefly due the recognition of the association between adrenal tumours and sex change in women which has led to the diagnosis and cure of a number of cases, and one of the last things which interested him before he had to give up work was a remarkable example of precocious adrenal virilism in a male infant. Another matter of considerable importance which he, Dr. Howel Evans and their associates have recently developed is the increase in the number of platelets in the blood following operations, childbirth, and probably tissue injury in general which must have a good deal to do with post-operative thrombosis. In earlier years Glynn investigated the opsonic technique and brought forward the simple plan of counting bacteria in a hæmocytometer chamber which has been widely used. Dysentery bacilli, the pneumococcus and pneumonia, the meningococcus, and cerebro-spinal meningitis at one time or another had his effective attention; with lamb dysentery he was as energetic but less successful. An elaborate inquiry into the results obtained in the venereal clinic showed that the addition of mercurial treatment to a course of arsenicals was undesirable. It is no formality to say that scientific medicine will deeply feel the loss of Glynn just when he had reached the height of his productive powers.

Glynn was not married. He lived in the famous house, 62, Rodney-street, where Gladstone was born, with few interests beyond pathology and the motor-car which he drove so furiously. For the last few years of his life he was coping courageously with the disease which ultimately killed him.

LODGE MOOR HOSPITAL, SHEFFIELD.—Extensions to this institution were opened on Friday in last week by Sir George Newman, Chief Medical Officer of the Ministry of Health. The additions include two ward units and an isolation block. Each unit has two wards of 12 beds and two single wards, making a total of 26 beds. With the six wards in the isolation block the accommodation will thus be increased by a total of 58 beds. The one-storey buildings are arranged in V-shape to obtain the maximum of sunshine, and the central duty room is so placed that there is a clear view of every bed in the unit. The extension is part of a larger scheme, upon which work has already been begun.

CHARING CROSS HOSPITAL.—The annual report repeats the claim that this is the lowest in cost per bed of any London hospital. Its 4030 in-patients cost £12 2*s.* 7*d.* each for an average stay of 21 days, and there were 27,689 new out-patients who cost an average of 7*s.* 4*d.* each. There was a surplus of £3000 of income over expenditure, and there is no debt. The site and buildings of the Westminster Ophthalmic Hospital, which were bought for £70,000, will shortly be available, and of the £100,000 which will be the total cost of purchase and equipment, all but £11,000 had been obtained at the end of December last. Owing to the increase in the number of accident cases it will shortly be necessary to enlarge the casualty department. When this has been accomplished attention will be turned to the provision of a new nurses' home elsewhere, thus releasing the Chandos-street block for private paying patients.

Correspondence.

"Audi alteram partem."

RELATION OF THE TONSILS TO RHEUMATIC CONDITIONS.

To the Editor of THE LANCET.

SIR,—The remarks of Mr. Macleod Yearsley in your last issue appear to sum up the general consensus of opinion upon the rôle of the tonsils in acute rheumatism and allied conditions. I have had the opportunity of removing by enucleation large numbers of tonsils for these conditions, having excised all septic tonsils at three large hospitals wherever acute rheumatism, chronic rheumatism, cardiac disease, or chorea were discovered; also for septic eye conditions and tuberculosis more recently. I have, of course, strictly confined myself to unhealthy tonsils, the combination of secretion from the follicles and the circumfaucial infection-ring being my test of a septic tonsil. Septic teeth have been cleared in all cases. I can state very definitely that the perfect "T and A enucleation" does not prevent acute or chronic rheumatism or chorea, though the patient is all the better for the operation (overlooking one unfortunate stirring up of a septic endocarditis). This is especially so in the case of chorea, where many patients have lost their tonsils previously and elsewhere, or may be admitted with a recurrence.

My object in writing is to ask, Can we expect to affect acute rheumatism or chorea by removing the faucial and nasopharyngeal tonsils, whilst leaving behind the lingual tonsil—often visibly septic, and certainly a source of trouble in the upper respiratory tract? Have any of your readers experience of the inclusion of the lingual tonsil in the enucleation operation as a routine? Its complete enucleation is difficult and may give rise to secondary hæmorrhage in a situation difficult to deal with; but to leave it is to leave what in my opinion has been the cause of much infection.

I am, Sir, yours faithfully,
Manchester, Sept. 27th, 1929. WILLIAM WILSON.

To the Editor of THE LANCET.

SIR,—I am in complete agreement with Mr. Macleod Yearsley in his belief that the most frequent source of rheumatism, septic tonsils and septic teeth, lies in the toxæmia which results from chronic intestinal intoxication—so far, that is, as the chronic form of rheumatism is concerned. I do not know enough about the acute to discuss it. I also agree with Mr. Yearsley's opinion that apart from a certain general improvement that must necessarily accrue from the removal of a definitely septic focus, tonsillectomy has no influence upon the incidence or cause of any rheumatic condition, either acute or chronic. My belief that chronic rheumatism is merely a symptom of intestinal stasis or chronic autotoxæmia from the bowel is based on personal observations extending over a period of nearly 20 years. In chronic rheumatic states I have seen cases innumerable where tonsils have been expertly enucleated, and yet the rheumatism has persisted. I have also seen many mouths swept clean of all teeth with no real benefit to the rheumatism. I was therefore driven to the conclusion that there was another factor behind both septic teeth and unhealthy tonsils, and, as the result of treatment of the alimentary canal, I was further driven to the conclusion that here lay the source most likely producing the state existing in the teeth and in the tonsils, and certainly the source of the rheumatism.

I also found that practically every case of intestinal stasis (as proved clinically, by bacteriological examination of the fæces, and by a bismuth transit and a barium enema) was the possessor of unhealthy tonsils and in many cases of septic teeth. But as on having the teeth and the tonsils removed the rheumatism still remained in statu quo, an active onslaught on the bowel was made. The result of this was that the teeth (I do not refer to chronic *apical* dental sepsis) with ordinary hygienic care cleared up and the signs of tonsillar infection greatly receded. What was more surprising was that the rheumatism vanished, even in cases regarded as almost hopelessly chronic. Treated *from the source of infection* I know of no condition that will yield more satisfactorily to correct treatment; the results are often dramatic in the, apparently, most intractable of cases. But the treatment must be complete and thorough.

I am, Sir, yours faithfully,

A. GRAHAM-STEWART.

Ulster-place, N.W., Sept. 28th, 1929.

VITAL STAINING OF NEOPLASTIC TISSUES.

To the Editor of THE LANCET.

SIR,—In his most interesting paper in your issue of Sept. 21st (p. 603) Mr. Burrows suggests one therapeutic application of the phenomena he describes. I venture to suggest another, capable of experimental proof or disproof. With present operative procedures for neoplastic diseases the excisions have, for well-known reasons, to be very extensive and encroaching widely into normal tissues. If such neoplastic tissues are capable of differentiation by the various dyes, the dye could be injected prior to operation and the actual infiltration into normal tissues could be determined on operation and, in many cases, the field of removal be considerably reduced. Other applications would be in cases of severe burns and senile gangrene to determine definitely the line of demarcation.

In a paper by Mogilnitsky and Podljaschux, shortly to be published in *Die Fortschritte auf dem Gebiete der Röntgenstrahlen*, these investigators have found that trypan-blue is retained in the brains of dogs and rabbits which have been submitted to X rays. X rays (and doubtless γ rays) are, therefore, to be added to the list of irritants cited by Mr. Burrows, and any experiments he has made in this relationship would be of interest. The retention of dye after X ray treatment might confirm the view, held by many radiologists, that the beneficial results of such treatment is perhaps only due to reaction of tissues to irritation by the rays.

I am, Sir, yours faithfully,

BERNARD LEGGETT.

Romford-road, Forest Gate, Sept. 28th, 1929.

THE IMPORTANCE OF THE LIVER IN CHEMOTHERAPY.

To the Editor of THE LANCET.

SIR,—The article by Dr. L. Cunningham and Dr. M. M. Datnow in your last issue (p. 652) confirms, in the main, the work of our cancer research team on the effect of colloidal metals on the liver. There are some points, however, on which we are not in agreement. It is stated that lead selenide, amongst some other preparations, has little action on the liver of animals, but we observe in Table I. that the incidence of jaundice after lead selenide is about the same as after "S7." In our monograph on "Chemotherapeutic Researches on Cancer" published in July, 1928 (of which copies were sent to the Liverpool Medical Research Organisation at their request), the changes in the liver and other viscera are briefly noted; focal necrosis in the liver after lead selenide is recorded there. We have repeatedly found the same changes after the administration of active colloidal preparations of lead, thallium and thorium, differences are of degree only.

There is a risk that readers of this article might conclude that the hepatic factor could be ignored during treatment with colloidal lead selenide, "D4S." We find that we cannot afford to ignore the liver. For some hours before and after administration of "D4S" we give a very light carbohydrate diet. We find that fat digestion progressively deteriorates and that jaundice is readily provoked by a diet rich in fats; this jaundice readily yields to a fat-free diet. The evidence offered for the taking up of the colloid by the cells of the reticulo-endothelial system in the liver is inconclusive. We find that much lead is to be found in the liver in man and animals, much more than is to be found in the neoplasm, but we are not convinced that it is stored in the cells of the reticulo-endothelial system. Very similar granules to those figured are found after administration of many of the electro-negative colloids, even after non-metallic ones, such as the trypan blues. It is thought that these particles are often hæmosiderin derived from hæmolysis and the hæmorrhages which so frequently follow administration of these colloids. We and others have tried to prove that these particles are lead, but cannot obtain certainty.

I am, Sir, yours, faithfully,

A. T. TODD.

Bristol Royal Infirmary Cancer Research
Laboratories, Sept. 28th, 1929.

CONGENITAL ECTODERMAL DEFECT.

To the Editor of THE LANCET.

SIR,—In his article last week (p. 656) on congenital ectodermal defect, Prof. A. W. Falconer discusses the points of resemblance to "progeria." He refers to a case shown by Dr. Jean Smith (January, 1929) at the Royal Society of Medicine in which the diagnosis of progeria had been at first suggested. I venture to draw his attention to a case shown at the same Society in October, 1927, by Dr. C. F. Harris as one of progeria, which, however, was almost certainly not one of progeria but one of congenital ectodermal defect.[1] I am, Sir, yours faithfully,

London, W., Sept. 28th, 1929. F. PARKES WEBER.

VACCINATION AND ENCEPHALITIS.

To the Editor of THE LANCET.

SIR,—I was much interested to read in your issue of July 27th (p. 185) the report of two cases of encephalitis supposed to be the result of vaccination against small-pox. In my vast experience in India this complication is unheard of. We do get, not seldom, a general or localised eruption similar to vaccinia, but this the vaccinated child, if kept clean, gets over in a couple of weeks' time. May the encephalitis be not due to some condition present in the vaccinated person particularly if vaccinated at an age beyond that of infancy or childhood as happened in these two cases? Is it because we practise vaccination in infancy that such complications as encephalitis are totally absent in this country?

I am, Sir, yours faithfully,

A. F. WINNINGTON DA COSTA.

Sept. 9th, 1929. Civil Surgeon, Bilaspur, C.P. (India).

THE BRITISH COLLEGE OF OBSTETRICIANS AND GYNÆCOLOGISTS.

To the Editor of THE LANCET.

SIR,—In the issue of the *Times* of Sept. 27th, in which the composition of the Council of the British College of Obstetricians and Gynæcologists was set forth, my name was included in the list of Councillors. This was a mistake, and I should be obliged if you would publish this letter of correction.

I am, Sir, yours faithfully,

VICTOR BONNEY.

Devonshire-place, W., Sept. 28th, 1929.

MEDICAL SICKNESS, ACCIDENT AND LIFE ASSURANCE SOCIETY, LIMITED.

To the Editor of THE LANCET.

SIR,—The annual general meeting of this Society will be held on Monday afternoon next, Oct. 7th. Three important resolutions, of which due notice has been given, are to be moved at this meeting, but have been withheld from the agenda on the notice calling the meeting. The members of the Society have thus not been made fully aware of all the resolutions on which a vote will be taken. Nevertheless the Board, on finding that the proposer of a resolution, making an age-limit for directors, had received proxies supporting his resolution, have now issued official proxies in their own favour. Official proxies have to my knowledge never been sent out before. Last year when the re-election of a director was contested, the Board decided that it would not be justified in incurring the expense of sending out proxies. How can they justify themselves in doing so this year? I submit that it is not fair dealing for the Board to attempt to get votes from members without giving them full information.

I am, Sir, yours faithfully,
HARVEY HILLIARD.

Hyde Park Gardens, W., Oct. 1st, 1929.

A CASE OF SEVERE SNAKE-BITE IN THE WEST OF ENGLAND.

To the Editor of THE LANCET.

SIR,—A woman was lately walking down some cliffs near Plymouth when she was bitten by a snake on the dorsal aspect of her foot. She immediately had it sucked and a tight handkerchief was put round her ankle. In five minutes, however, a large swelling had developed and she could barely struggle down to a boat to be conveyed back to Plymouth. In a quarter of an hour from being bitten the foot and ankle were very much swollen and she experienced a "tight" feeling across the chest and difficulty in respiration. Her lips swelled up, she began to vomit, and in half an hour she was completely collapsed with a choking feeling in the throat, due to some œdema of the glottis. She was practically pulseless, cold, and sweating; she had incessant vomiting and diarrhœa; her face and lips were swollen enormously and the whole leg was enlarged with a slight vesicular eruption becoming visible. She was given injections of adrenalin (which relieved the throat condition), strychnine, and pituitrin and large quantities of brandy to drink, and was moved to a nursing-home, where the wound was incised and a clot turned out. It was then evident that the wound had directly involved a small vein. Potassium permanganate was rubbed in locally and stimulant injections were continued until her pulse gradually returned six hours later. Within the next two days she rapidly improved; her pulse became normal and no rise in temperature was charted. The leg, however, continued to swell with pitting œdema, and femoral thrombosis was suspected. After four days the swelling suddenly gave way to blotchy discoloration, obviously due to extravasation of blood into the tissues. After this recovery was uneventful.

Does the English adder venom commonly cause any thrombosis directly, or does it produce endothelial damage leading to extravasation into the tissues?

I am, Sir, yours faithfully,
Sept. 29th, 1929. D. W. B.

HOSPITAL FOR TROPICAL DISEASES.—The space liberated in the premises in Endsleigh-gardens by the removal of the London School of Hygiene and Tropical Medicine, which shared them with the Hospital for Tropical Diseases, is being utilised for the enlargement of the hospital. New wards, a pathological laboratory, and a clinical lecture theatre are being provided. In addition to treating tropical diseases, the hospital teaches medical men who intend to practise in the tropics and the students of the School of Tropical Medicine.

Medical News.

UNIVERSITY OF LEEDS.—At recent examinations the following candidates were successful:—

M.D.

R. Chester, M. S. Scott, and A. Sourasky.

FINAL EXAMINATION FOR M.B., CH.B.

Part I.—F. B. T. T. Drake, W. R. Everatt, G. Hirst, J. Rabinovitch, and M. I. Silverton.

Part II.—W. H. Craven, H. Denton, C. H. Foster, W. L. Hardman, J. N. Mill, L. Hoyle, C. Ponledel, S. Rosenberg, L. Seaton, W. E. Smart, E. J. Wayne, and J. W. Whitworth.

Part III.—*E. J. Wayne, †C. H. Foster, †W. L. Hardman, T. G. Clarke, H. Denton, S. K. Foster, W. Greaves, L. Hoyle, H. T. Knowles, C. Ponledel, Margaret F. Robertson, Mary G. Shawe, and J. W. Whitworth.

* First-class honours.
† Second-class honours.

D.P.H.

Kathleen M. Peacock and Edith A. Whitney.

D.P.M.

C. L. Copeland, W. Fraser, D. T. Gemmell, and J. J. O'Riordan.

FINAL EXAMINATION FOR L.D.S.

Part II.—J. Dobkin, J. W. B. Hargreaves, and Margaret E. M. Hey.

The William Hey Medal for the most distinguished medical graduate of the year has been awarded to Mr. Edward Johnson Wayne. Mr. Wayne has also been awarded the West Riding Panel Practitioners' Prize for proficiency in Medicine.

UNIVERSITY OF LONDON: *Forthcoming Lectures.*—Fixtures for the coming session include five lectures on Blood Plasma and Platelets, by Mr. J. W. Pickering, D.Sc., at King's College, at 5 P.M., on Tuesdays, from Oct. 8th to Nov. 5th; four lectures on the Physiology of the Fœtus, by Dr. A. St. G. Huggett, at St. Thomas's Hospital Medical School, at 5 P.M., on Tuesdays, from Oct. 8th to 29th; four on Secretion of the Digestive Juices, by Dr. R. J. Brocklehurst, at University College, at 5 P.M., on Mondays, from Oct. 14th to Nov. 4th; three on (1) Seasonal Variations of Epidemic Diseases, (2) Milk Epidemics, and (3) Diphtheria Toxin and Antitoxin, by Prof. Thorvald Madsen, of Copenhagen, at the London School of Hygiene and Tropical Medicine, at 6 P.M., on Oct. 14th, 16th, and 18th; four on the Metabolism of the Carbohydrates and Fats, by Mr. J. A. Hewitt, D.Sc., at King's College, at 5 P.M., on Thursdays, from Oct. 17th to Nov. 7th; and six on Human Nutrition, by Prof. V. H. Mottram, at King's College for Household and Social Science, at 5 P.M., on Fridays, from Oct. 18th to Nov. 22nd. Admission to these lectures is free, without ticket.

University of London: University College.—A farewell dinner to Sir Gregory Foster, who retires from the position of Provost of the College on Dec. 31st, will be given by past and present students on Friday, Dec. 20th, at a place in London to be determined later. Those who wish to attend are asked to inform Mr. B. N. Parker, hon. secretary, Old Students' Association, at the College, without delay, adding particulars of their Faculty and dates of student years at the College.

Mr. F. E. Smith, D.Sc., F.R.S., Director of Scientific Research at the Admiralty, has been appointed Secretary to the Committee of the Privy Council for Scientific and Industrial Research, on the resignation of Mr. H. T. Tizard, F.R.S.

CLINICAL LECTURES AT MAUDSLEY HOSPITAL.—A course of clinical lectures will be given at the Maudsley Hospital, Denmark Hill, London, S.E., from Oct. 28th, at 2.30 P.M. daily, except Saturdays. The lecturers will be on Mondays, Dr. A. J. Lewis, on Mental Symptoms and their Genesis; on Tuesdays, Dr. T. Tennent, on Nervous Disorders in Children; on Wednesdays, Dr. Edward Mapother, on Neurotic and Psychotic Syndromes; on Thursdays, Dr. J. S. Harris, on Relations of Mental Disorder to Physical Conditions; and on Fridays, Dr. F. L. Golla, Captain S. A. Mann, and Mr. C. Geary, on the Pathology of Mental Disorders, Laboratory Methods and their Place in Diagnosis, and the Pathology of the Nervous System, respectively. In addition, a discussion on cases in the hospital is held in the wards every Monday, Tuesday, and Thursday at noon, all these lectures and discussions being open to medical practitioners without fee. A course for the Diploma in Psychological Medicine will begin in January. Inquiries should be addressed to the Director of the Central Pathological Laboratory at the hospital.

Royal Dental Hospital of London: *School of Dental Surgery.*—Dr. Boyd S. Gardner, of the Mayo Clinic, Rochester, U.S.A., will give a lecture at this School in Leicester-square on Monday, Nov. 4th, at 6 P.M. His subject will be "the relationship between medicine and dentistry, emphasising the routine use of the X ray from both a pre- and post-operative standpoint; the necessity of an improved extracting technique, and the significance of laboratory investigation."

Mr. Arthur Greenwood, Minister of Health, has appointed Mr. S. F. S. Hearder to be his assistant private secretary. Miss Susan Lawrence, Parliamentary Secretary to the Ministry of Health, has appointed Mr. G. C. North to be her private secretary; and Mr. E. R. Forber, Deputy Secretary to the Ministry, has appointed Mr. E. C. H. Salmon to be his private secretary.

Royal Albert Institution Extension.—The foundation-stone of a new building to be called the Welch Memorial Home was laid on Sept. 27th by Lord Richard Cavendish, Chairman of the Central Committee. This new addition to the Royal Albert Institution at Preston will cost about £10,000, and will provide accommodation for about 50 senior boys, together with the staff. It will commemorate the late Mr. William Gibbins Welch, of Hampson, Lancaster, who was associated for half a century with the management of the institution.

London Medical Exhibition.—The exhibition will be held this year at the new hall of the Royal Horticultural Society, Greycoat-street, Westminster, London, S.W., during the week beginning on Oct. 14th. It will be open daily from Monday to Friday inclusive from 12 noon till 6.30 P.M. The exhibition has now been an annual fixture for a quarter of a century, but the organisers, who managed the exhibitions of the Seventeenth International Congress of Medicine, 1913, and the Fifth Clinical Congress of Surgeons, 1914, anticipate that this year's show of drugs and surgical appliances will be the largest yet held. One attraction will certainly be the size and convenience of the new hall in which it is to be held, for all exhibits will be on one level and well lighted. Admission will be confined to doctors, for whose recreation tea and orchestral music will be provided in a spacious reception room overlooking the hall. Practitioners who have not received invitation cards can obtain them on application to the Secretary, the London Medical Exhibition, 194–200, Bishopsgate, London, E.C. 2, or at the hall during the exhibition week.

Donations and Bequests.—Mr. Keith R. Maitland, W.S., of Edinburgh, left, subject to a life-rent, £2000 each to the Royal Infirmary, Edinburgh, and Royal Edinburgh Hospital for Sick Children; £1000 each to the Convalescent House, Murrayfield; Royal Edinburgh Hospital for Incurables; Royal Blind Asylum and School, Edinburgh; Governesses' Benevolent Society of Scotland; Society for Relief of Indigent Gentlewomen of Scotland; and Queen Victoria's Jubilee Institute for Nurses (Scottish branch).—Mr. John Thomas Chadwick, of Beech-road, Stockport, left, on the death of his sisters, £3000 to Stockport Infirmary and £1000 each to Stockport Working Lads' Association, Stockport Sick Poor and Private Nursing Association, Stockport Institute for the Blind, Deaf, and Dumb, and St. Dunstan's Hostel for the Blind. The ultimate residue in trust for British spa treatment of poor persons, natives, or residents of Stockport, suffering from arthritis, sciatica, rheumatism, neuritis, or gout.—Mr. Thomas Morgan, of the Woodlands, Treforest, Glamorgan, besides other bequests, left £1000 each to Pontypridd Cottage Hospital and to King Edward VII. Hospital, Cardiff.—Miss Margaret Cummings Innes, of St. Swithin's-street, Aberdeen, left £2000 to St. Dunstan's Hostel for Blinded Sailors and Soldiers; £1000 each to the Aberdeen Royal Infirmary, the Aberdeen Royal Hospital for Sick Children, and the Morningfield Hospital, Aberdeen, with some further residual interest.—Mr. Henry Bacon Atkinson, of Adelaide Mansions, Hove, and Knyveton-road, Bournemouth, left £600 to the Sussex County Hospital, and £100 each to the Sheffield General Infirmary, the Sheffield Institute for the Blind, and the Sheffield Royal Hospital and Dispensary.—Mr. James Fleming Fyfe-Jamieson, of Ruthven, Perthshire, left a legacy of £1500 to endow a bed, called the Fyfe-Jamieson bed, in Viewpark Nursing Home, and £5000 to charity.—Mrs. Anna Nockold, of Goffs Oak Villa, Cheshunt, Herts, left over £13,000 to various institutions, including £2000 to Dr. Barnardo's Homes, and £2500 each to the London Temperance Hospital and the Blinded Sailors and Soldiers After-Care Organisation (St. Dunstan's, Regent's Park).—Bequests of over £31,000 were left to charities by the late Mr. Alexander Fowler Roberts, of Fairnilee, Galashiels, manufacturer, including £5000 to the Edinburgh Royal Infirmary and £2000 to the Longmore Hospital, Edinburgh.

The Minister of Health has appointed a Departmental Committee "to inquire into the administration of the laws relating to the relief of the casual poor and to make recommendations having special regard to the assistance of persons genuinely seeking work and to persons suffering from physical or mental disability." The members of the committee are: the Rev. L. R. Phelps (chairman), Mr. J. A. Dale, Mr. Douglas Hacking, M.P., Sir Arthur Lowry, Dr. A. C. Parsons, Mr. A. Paterson, Mr. A. Shepherd, Mrs. Wintringham, J.P., with Mr. L. N. Ure, of the Ministry of Health, as secretary.

Royal Medical Benevolent Fund.—A service in aid of this fund will be held at Liverpool Cathedral at 8 P.M. on Oct. 13th. The Rt. Rev. E. C. Pearce, Bishop of Derby, will preach the sermon, and the Lord and Lady Mayoress will attend. Doctors and their friends are invited to this service. Tickets may be obtained from the local hon. secretary, 28, Rodney-street, Liverpool.

At the two recent meetings of the committee £855 was voted in grants to 64 applicants, and £537 was voted in annuities to 20 beneficiaries over 60 years of age. The following were some of the cases helped with annuities:—

M.R.C.S., aged 79, who owing to deafness and age is unable to follow his profession. His wife's savings have been exhausted by the claims made upon him by his family, and his only income is £52 a year contributed by two nephews. Voted annuity of £70.

L.R.C.P. & S., aged 79, whose savings have all been exhausted. She is the inmate of a home where she has to pay rent of £19 10s. Her only income is the Old Age Pension £26. Voted annuity of £36.

Widow of F.F.P.S., aged 75, who lives with her married daughter whose husband is a Post-office sorter. The widow pays £32 10s. a year to her daughter for board and lodging and her income is Old Age Pension £26. Voted annuity of £36.

Widow of M.B., aged 68, whose daughter is earning 30s. a week and who contributes £52 a year to her mother being her only income. Voted annuity of £26.

Widow of M.R.C.S., aged 74, unable to work owing to her age and has only the Old Age Pension. Voted annuity of £26.

Daughter of M.R.C.S. aged 69. Has an income from investments of £34 a year. Voted an annuity of £35.

Subscriptions and donations should be sent to the hon. treasurer, Sir Charters Symonds, at 11, Chandos-street, Cavendish-square, London, W. 1.

Liverpool School of Tropical Medicine.—The Mary Kingsley Medal, which is conferred in recognition of distinguished scientific achievement, has been awarded to Dr. G. Carmichael Low, Senior Physician to the Hospital for Tropical Diseases, London; Dr. Guy A. K. Marshall, Director of the Imperial Bureau of Entomology; Emeritus Prof. Robert Newstead, F.R.S., formerly Dutton Memorial Professor of Entomology in the Liverpool School of Tropical Medicine; Dr. A. T. Stanton, Chief Medical Adviser to the Secretary of State for the Colonies; Emeritus Prof. J. W. W. Stephens, F.R.S., formerly Professor of Tropical Medicine in the Liverpool School of Tropical Medicine; and Dr. C. M. Wenyon, Director-in-Chief of the Wellcome Bureau of Scientific Research. The medals will be presented by the chairman of the School, Sir Frederick Bowring, at a banquet in Liverpool on Friday, Oct. 11th.

St. Bartholomew's Hospital Dinner.—The annual dinner of Old Students was held in the Great Hall of the Hospital on the evening of Oct. 1st, with Sir Frederick Andrewes in the chair, the size of the gathering being favourably influenced by the post-graduate course on radium which is in progress at the school. To many of those who attended the Hall itself was almost a novelty, for not only had electric light been installed, but the floor had been relaid and the ceiling redecorated as part of the work of general reconstruction which is going on throughout the hospital precincts. The dinner itself, which was largely attended, was of the usual domestic character, but the absence of a toast list did not prevent the treasurer, Lord Stanmore, from proposing "The Chairman," a toast which was drunk with musical honours. In reviewing the main events of the year Sir Frederick alluded with regret to the unusual number of deaths of seniors, including Church, Duckworth, Cumberbatch, Bowlby, and Harding. He then turned to the attraction of the moment, the new surgical block nearing completion and to be opened early next year. It was, he said, the last word in surgical luxury, alike for surgeon, dresser, nurse, and patient. Every surgeon had a self-contained floor, his own theatre, and his own private room, and last but not least, gas and oxygen was laid on from the basement to every operating table. Only about one-half of the sum of £200,000 spent on this block was yet in sight, but the Hospital had done well so far during its period of reconstruction which began nearly 30 years ago with the new buildings for out-patients, pathology, and nurses; for of the total £350,000 all but about £58,000 had been paid off in spite of the unfortunate reputation of being wealthy. An appeal would shortly be made jointly for the Hospital and College, the latter being now a corporate body capable of holding funds, although as yet wholly unendowed. He would like to see it able to pay adequate salaries and to subsidise research. As he sat down Sir Frederick's eye chanced on the panel which records the first gift made towards the building of the first wing of the present hospital in 1720, the donor being Sir Richard Brocas, Knight and Alderman, just two centuries ago. Besides the treasurer and the administrative staff of the hospital there were present as guests Sir Humphry Rolleston, Air Vice Marshal D. Munro, the Masters of six City companies, and Mr. T. A. Lodge, the architect of the new surgical block.

WESTMINSTER HOSPITAL DINNER.—On Oct. 1st about 130 past and present students dined together at Grosvenor House, Park-lane, under the genial chairmanship of Mr. Stanley Dodd, who was supported by Sir James Purves-Stewart, Dr. F. N. Kay Menzies, Dr. A. S. Woodwark, Dr. F. F. Bond, Dr. Florence Barrie Lambert, Mr. de Salis (chairman of Springfield Mental Hospital), and Mr. A. E. W. Marshall. Mr. Marshall proposed the toast of the Medical School, of which he is chairman. He praised the energy of their dean, Dr. Woodwark, in organising post-graduate courses which were widely appreciated, especially those on radium. Dr. Woodwark, in response, said the hospital was now starting on its 210th year and the school on its 96th, and that last year it had its record number of students. A great event during the year was the acquisition, mainly through the kindness of Mr. Woolf Barry, Colonel Bulkeley, and Dr. Reginald Worth (medical superintendent of Springfield Mental Hospital) of a fine sports pavilion which could be reached from the hospital in half an hour. The school was looking to the future with every confidence in its capacity to provide an excellent medical training combined with every facility for athletics. The chairman submitted the toast of Past and Present Students, recalling the days when students had not the amenities enjoyed by the present generation. He ended with wise and breezy advice to those who were now beginning their careers. Dr. F. F. Bond and Mr. A. S. Daniel, the hon. secretary of the Students' Club, replied to this toast. The latter voiced the gratitude of the students to those who had combined to provide them with a sports ground and pavilion. Mr. de Salis expressed the pleasure felt by the Springfield Mental Hospital Committee in helping to supply proper facilities for the students' recreation. Sir James Purves-Stewart proposed the Guests, making mention of the work of Dr. Barrie Lambert as chairman of that committee of the L.C.C. of which Dr. Menzies was executive officer, and of the activities of Mr. K. W. Barry, as chairman of the House Committee, and of Mr. de Salis in connexion with the mental hospital with which the school was associated. Dr. Menzies replied. Mr. Rock Carling proposed the Chairman, whose response ended the formal part of a happy evening.

MIDDLESEX HOSPITAL DINNER.—At the annual dinner held at the Savoy Hotel on Oct. 1st the chairman, Mr. A. E. Webb-Johnson, said that within a few weeks patients would be transferred to the new west wing. The two wards in the new surgical wing were to bear the names of Sir Charles Bell, founder of the Medical School, and Sir John Bland-Sutton. When the present work was complete the hospital would have, among other things, a new nurses' home, residents' house, power-house, pay-block, and institute of biochemistry, whilst the chapel would be enlarged. Nothing now remained but to pull down the right wing and start again; £300,000 would see the job through, and anyone who was at present feeling scared about financial speculation could not do better than choose a good safe investment such as the Middlesex Hospital. The sum of £300,000 given anonymously for the nurses' home was, he thought, one of the greatest if not the greatest gift ever received by a hospital from an individual during his lifetime. Retired nurses were getting the benefit of Dr. Essex Wynter's cottages, 11 of which were now occupied. After offering a cordial welcome to the new matron, Mr. Webb-Johnson referred to the death of Dr. F. J. Wethered, and spoke of the help which the hospital had had from the late Mr. Bernhard Baron. The retirement of Mr. Walter Kewley, the tried and trusted secretary of the hospital, had been a source of great regret, but it was to be hoped that his successor, Mr. S. R. C. Plimsoll, as the son of his father, would keep the hospital well above the safety line. Turning to the Medical School the chairman recalled that during the King's illness the scientific investigations had been done by Middlesex men, and congratulated Dr. L. E. H. Whitby and Prof. E. C. Dodds on their honours. Perhaps, however, the man most entitled to pride in these successes of his students was Prof. McIntosh. During the year the hospital had won two inter-hospital cups, for soccer and sailing. Mr. Eric Pearce Gould had retired from the post of Dean, which he had held with so much distinction to himself and so much benefit to others. His achievements had been many, but fate was ironical and he would probably go down to history as the man who got a drink licence for the School. Mr. Webb-Johnson concluded by wishing every success to the new dean, Dr. T. Izod Bennett. In proposing the toast of the hospital he expressed his admiration for Prince Arthur of Connaught for accepting the chairmanship when he knew what difficult problems had to be faced. In reply to the toast Prince Arthur said there was every reason for optimism. The general public, however, was apt to look on hospitals as rather frightening and repellent, and he wished they could be taught to change this view, and regard them not only as part of the national life, but as something friendly and welcoming. Responding for the Medical School, Dr. Izod Bennett made some amusing observations on the repressed romanticism of neurological surgeons, and Mr. J. N. O'Reilly produced witticisms which in themselves justified his selection as one-third of the Broderip scholar. Mr. Pearce Gould, proposing the toast of the Guests, pointed out that the guests of hospitals usually came in for rather peculiar hospitality. If he had taken a complete history of all the guests at this dinner what a tale he could unfold! Viscount Lee of Fareham, in his reply, said that the profusion of doctors present reminded him of the remark of a poor old woman from London who saw the sea for the first time and said: "My, but it's good to see enough of anything for once." He complained of the dog Latin affected only (he thought) by doctors and gardeners, and mentioned that his popularity seemed to have increased in hospital circles since it became known that, as chairman of the Radium Commission, he possessed a four-gramme bomb of radium. Lieut.-General H. B. Fawcus, Director-General of the Army Medical Services, spoke of the need for coöperation between civilian and military medicine in time of peace. Sir Arnold Lawson proposed the health of the chairman, whom he compared to Moses in his capacity for striking things out of rocks—not, however, by force, but by kind words and winning smiles. This toast was drunk with musical honours, and when Mr. Webb-Johnson replied he did not hesitate to tell Lord Lee that the four-gramme bomb could be safely entrusted to the Middlesex Hospital.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

TUESDAY, Oct. 8th.—5 P.M., THERAPEUTICS. Dr. Philip Hamill: Some Principles of Therapeutics (Presidential address).

THURSDAY.—8.30 P.M., NEUROLOGY. Dr. Gordon Holmes: Dissociation of the Ocular Movements (Presidential address).

FRIDAY.—5.30 P.M., CLINICAL. (Cases at 5 P.M.) Dr. H. V. Morlock: Case of Pseudo-leukæmia. Mr. Cecil P. G. Wakeley: (1) Case of Congenital Shortening of the Femur. (2) Two Cases of Kohler's Disease. (3) Tuberculous Knee in a Boy of Ten. Dr. Gerald Slot: (1) Case of Actinomycosis. (2) Spinal Tumour. Mr. H. C. Edwards: Nævus of the Tongue. Dr. Dorothy Hare: Subacute Multiple Arthritis with Fibrous Nodules. Other cases will be shown. 8.30 P.M., OPHTHALMOLOGY. (Cases at 8 P.M.) Papers: Mr. E. E. Maddox: Demonstration of the Cheiroscope. Miss Rosa Ford: Some Ocular Complication of Nasal Sepsis. Cases and Specimens: Mr. Foster Moore: Case of Blue Sclerotics. Mr. J. Cole Marshall: Cystic Adenoma of the Conjunctiva. Mr. Humphrey Neame: Case of Gunshot Wound of Eyeball with Pellet Remaining in the Vitreous. Other cases will be shown.

SOCIETY FOR THE STUDY OF INEBRIETY.

TUESDAY, Oct. 8th.—4 P.M. (In the Great Hall of the British Medical Association House, Tavistock-square, London, W.C.). Sir Josiah Stamp: Alcohol as an Economic Factor. (Norman Kerr Memorial Lecture.)

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Oct. 7th, to SATURDAY, Oct. 12th.—PRINCE OF WALES'S HOSPITAL, Tottenham, N. Tues., 2.30 P.M., Dr. Browning Alexander (Ward Round). Thurs., 2 P.M., Mr. H. W. Carson (O.P. Demonstration. No fee).—NATIONAL HOSPITAL FOR DISEASES OF THE HEART, Westmoreland-street, W. Intensive Course for two weeks. Limited to an entry of 20.—LONDON SCHOOL OF

HYGIENE AND TROPICAL MEDICINE, Endsleigh-gardens, W.C. Tues. and Thurs., at 2 P.M., lecture-demonstrations by Dr. Carmichael Low and Dr. Manson-Bahr. Further particulars from the Fellowship of Medicine.

NATIONAL ASSOCIATION FOR THE PREVENTION OF TUBERCULOSIS: Annual Conference at Newcastle-on-Tyne.

THURSDAY, Oct. 10th.—10.30 A.M. to 12.30 P.M., Mr. H. A. Mess, Ph.D.: Tuberculosis on Tyneside—A Sociological Survey. 2.30 P.M., Dr. Edouard Rist (Paris), Dr. A. F. Bernard Shaw, Dr. C. G. R. Goodwin, and Sir Thomas Oliver: The Factors that Produce Adult Pulmonary Tuberculosis.

FRIDAY.—10.30 A.M., Scheme of National Propaganda regarding Tuberculosis; Combined Treatment and Technical Education of Tuberculous Youths. 2.30 P.M., Sec. I.: *Teaching of Tuberculosis to Under-graduates*; Training of Tuberculosis Medical Officers. Sec. II.: Methods of Local Propaganda regarding Tuberculosis; Dentistry in relation to Tuberculosis.

SATURDAY.—9.30 A.M., Visits to Hospitals.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, Oct. 7th.—2.30 to 5 P.M.: Medical, Surgical and Gynæcological Clinics. Operations.

TUESDAY.—2.30 to 5 P.M.: Medical, Surgical, Ear, Nose and Throat Clinics. Operations.

WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin, and Eye Clinics. Operations.

THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, Nose, Throat and Ear Clinics. Operations.

FRIDAY.—10.30 A.M.: Throat, Nose and Ear Clinics. 2.30 to 5 P.M.: Surgical, Medical, and Children's Diseases Clinics. Operations.

NATIONAL HOSPITAL, Queen-square, W.C.

MONDAY, Oct. 7th.—12 noon., Dr. Greenfield: Pathology of Nervous System. 2 P.M., Dr. Riddoch: Out-patient Clinic. 3.30 P.M., Dr. Adie: Disseminated Sclerosis.

TUESDAY.—2 P.M., Dr. Walshe: Out-patient Clinic. 3.30 P.M., Dr. Critchley: Occupational Neuroses.

THURSDAY.—2 P.M., Dr. Kinnier Wilson: Out-patient Clinic. 3.30 P.M., Dr. Riddoch: Some Heredo-familial Diseases.

FRIDAY.—12 noon., Dr. Purdon Martin: Anatomy and Physiology of Nervous System. 2 P.M., Dr. Adie: Out-patient Clinic. 3.30 P.M., Mr. Elmquist: Demonstration of Re-educational Methods (in Exercise Room).

CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL, Gray's Inn-road, W.C.

MONDAY, Oct. 7th.—1.30 P.M.: Examination of the Mouth and Pharynx.

WEDNESDAY.—1.30 P.M.: Examination of the Larynx.

ST. PAUL'S HOSPITAL, Endell-street, W.C.

WEDNESDAY, Oct. 9th.—4.30 P.M., Dr. D. Thomson: Common *Infections of the Genito-urinary Tract.*

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

TUESDAY, Oct. 8th.—5 P.M., Dr. W. N. Goldsmith: Anatomy and Physiology of the Skin.

THURSDAY.—5 P.M., Dr. J. M. H. MacLeod: Morphology and Histopathology of Elementary Lesions.

INSTITUTE OF HYGIENE, 28, Portland-place, W.

WEDNESDAY, Oct. 9th.—3.30 P.M., Dr. J. F. Halls Dally: High Blood Pressure—What it is and How to Avoid it.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE.

TUESDAY, Oct. 8th.—4.15 P.M., Mr. H. H. Rayner: The Position of Surgery in the Treatment of Gastro-duodenal Ulceration.

FRIDAY.—4.15 P.M., Mr. C. W. W. Surridge: The Relation of the Medical Profession with Coroners.

Appointments.

KEELE, C. A., M.B., B.S., has been appointed Resident Medical Officer, Freemasons Hospital and Nursing Home, Fulham-road, S.W.

SHARPE, J., M.B., Ch.B. Glasg., D.P.H., Medical Officer to Lanarkshire Joint V.D. Committee.

Certifying Surgeons under the Factory and Workshop Acts: PLATT, A. H., L.R.C.P. Lond., M.R.C.S. (Acton and Ealing); and MARREN, J. P., M.B., Ch.B. R.U.I. (Clwt-y-bont Carnarvon).

Vacancies.

For further information refer to the advertisement columns.

Aberdeen Royal Mental Hospital.—Jun. Asst. P. £250.

Bangor, Carnarvonshire and Anglesey Infirmary.—H.S. £200.

Bath, Royal United Hospital.—H.P. At rate of £120.

Bermondsey Parish Hospital, Lower-road, Rotherhithe, S.E.—Res. Asst. M.O. At rate of £100.

Birkenhead General Hospital.—Cas. S. £100.

Birmingham, Dudley Road Hospital.—Jun. Asst. M.O. At rate £200.

Birmingham, Selly Oak Hospital.—Res. Physician. £400–£600. Also Cas. O. at rate of £200.

Birmingham and Midland Ear and Throat Hospital.—Asst. Surg. O. £300.

Birmingham, Queen's Hospital.—Med. Registrar. £200.

Bolingbroke Hospital, Wandsworth Common, S.W.—H.P. At rate of £120.

Bootle Borough Hospital, Derby-road.—Jun. M.O. £125.

Bootle County Borough of—Asst. School M.O. and Asst. M.O.H. £600.

Bradford Royal Eye and Ear Hospital.—Jun. H.S. £120.

Bury Infirmary, Lancs.—Sen. H.S. £250.

Carlisle, Cumberland Infirmary.—H.P. At rate of £155.

Carlisle, Cumberland, and Westmorland Mental Hospital, Garlands.—Jun. Asst. M.O. £350.

Carmarthen Joint Counties Mental Hospital.—Jun. Asst. M.O. £300.

Cardiff City Mental Hospital, Whitchurch. — Post-Graduate Research Studentship. £100

Central London Throat, Nose and Ear Hospital, Gray's Inn-road, W.C.—Hon. Chief Clin. Assts.

Darlington County Borough —Deputy M.O.H. £750.

Doncaster Royal Infirmary.—Third H.S. At rate of £150.

Evelina Hospital for Children, Southwark, S.E.—H.P. At rate of £120.

Exeter, Royal Devon and Exeter Hospital.—Aural H.S. and Cas. O. At rate of £120. Also Hon. Physician.

Folkestone, Royal Victoria Hospital.—Sen. and Jun. Res. M.O.'s. At rate of £125 and £100 respectively.

Gloucester, Gloucestershire Royal Infirmary, &c.—Hon. S. to Ear, Nose and Throat Dept.

Great Yarmouth General Hospital.—Sen. H.S. £150. Also Jun. H.S. £100.

Halifax Royal Infirmary.—Third H.S. At rate of £100.

Hampstead General and North-West London Hospital, Haverstock Hill, N.W.—H.S. Also Cas. M.O. and Cas. Surg. O. Each at rate of £100.

Highgate Hospital, Dartmouth-park Hill, N.—Third Asst. M.O. £350.

Hospital for Consumption and Diseases of the Chest, Brompton, S.W.—H.P. At rate of £50.

Hospital for Epilepsy and Paralysis, Maida Vale, W.—Res. M.O. Also H.P. At rate of £150 and £100 respectively.

Hull Royal Infirmary.—Third H.S. Also Asst. H.P. At rate of £150 and £130 respectively.

Inverness Northern Infirmary.—Hon. Radiologist.

Islington Dispensary, 303, Upper-street, N.—Res. M.O. £400.

Larbert, Stirling District Mental Hospital.—Third Asst. M.O. £250.

Leicester Royal Infirmary.—Hon. Asst. Ophthal. S.

Liphook, Hants, King George's Sanatorium for Sailors.—Asst. M.O. At rate of £200.

Maidstone, West Kent General Hospital.—H.S. At rate of £220.

Manchester Royal Infirmary.—H.S. for Special Depts. At rate of £50.

Manchester, St. Mary's Hospital—Four H.S.'s. Each at rate of £50.

Manchester, Salford Royal Hospital.—Cas. H.S. At rate of £125.

Margate, Royal Sea Bathing Hospital.—H.S. At rate of £200.

Margaret-street Hospital for Consumption, 26, Margaret-street, W.—Hon. Asst. Physician.

Metropolitan Ear, Nose, and Throat Hospital.—H.S. £150.

Metropolitan Hospital, Kingsland-road, E.—H.P.'s, H.S's, &c. Each at rate of £100.

Miller General Hospital, Greenwich-road, S.E.—Out-patient Officer. At rate of £150.

Newcastle-upon-Tyne Eye Hospital.—Hon. Res. H.S. £200.

North Middlesex Hospital, Edmonton, N.—Second Asst. S. £500.

Norwich, Norfolk and Norwich Hospital.—H.P. £120.

Nottingham City Mental Hospital.—Jun. Asst. M.O. £350 to £400.

Nottingham General Dispensary.—Res. Surg. £250.

Paddington Green Children's Hospital, W.—H.P. and H.S. Each at rate of £150. Also Anæsthetist, £75.

Rotherham Hospital.—H.P. £150.

Royal National Orthopædic Hospital, 234, Great Portland-street, W.—Hon. Asst. Surg. Also Surg. Registrars. Each £105.

Royal Naval Dental Service.—Dental Officers.

Salford Royal Hospital.—H.S. £125. Cas. H.S. £125.

St. Andrew's Hospital, Dollis Hill, N.W.—Sen. and Jun. Res. M.O.'s.

St. John's Hospital, Lewisham, S.E.—Res. Cas. O. and Res. H.P. Each at rate of £100.

St. Peter's Hospital for Stone, Henrietta-street, W.C.—Radiologist. £25.

Saint Mark's Hospital for Cancer, &c., City-road, E.C.—H.S. At rate of £75.

Salisbury General Infirmary.—Res. M.O. £150.

Sheffield, South Yorkshire Mental Hospital.—M.O. £400.

Southampton, Royal South Hants and Southampton Hospital.—Cas O. At rate of £120.

Stafford County Mental Hospital.—Second Asst. M.O. £600.
Sudan Medical Service.—M.O. £E720.
Sydney University, N.S.W.—Bosch Chair of Bacteriology. £1500.
Watford, Herts, Peace Memorial Hospital.—Res. M.O. At rate of £150.
West London Hospital, Hammersmith, W.—Hon. Registrar for Throat, Nose, and Ear Dept. House Officer for Children's Dept. At rate of £150. Asst. M.O. At rate of £450. Also three Jun. Asst. M.O's. Each at rate of £350.
Western Ophthalmic Hospital, Marylebone-road, N.W.—Sen. and Jun. Non-Res. H.S's. At rate of £150 and £100 respectively.
Weston-super-Mare General Hospital.—Res. H.S. £130.
Westminster Hospital, Broad Sanctuary.—Wander Scholarship, &c. £250.
Willesden General Hospital, N.W.—Res. H.S. At rate of £100. Also Physician.
Winchester, Royal Hampshire County Hospital.—Res. H.S. At rate of £150.
Woolwich and District War Memorial Hospital, Shooter's Hill, S.E. Res. M.O. £175. Also H.S. At rate of £125.
Worcester General Infirmary.—Jun. Res. M.O. At rate of £120.

Births, Marriages, and Deaths.

BIRTHS.

LANSDOWN.—On Sept. 30th, at Woodcote Grove-road, Coulsdon, the wife of R. B. P. Lansdown, M.B., B.Ch., of a daughter.

MACKENNA.—On Sept. 25th, the wife of Dr. R. M. B. MacKenna, Liverpool, of a daughter.

MCLAGGAN.—On Sept. 29th, to Elsa V. McLaggan, M.B., B.S. (née Adams), wife of J. D. McLaggan, F.R.C.S., of 15, Wimpole-street, W.1—a son.

MARRIAGES.

DOWELL—DOMMEN.—On Sept. 17th, at St. Werburgh's, Derby, Dr. W. H. Dowell, of Castle Donington, to Henriette (Babs) Dommen, of Swiss Cottage, Tutbury.

HUDDY—JUMP.—On Sept. 21st, at the Parish Church, Wimbledon. E. C. Huddy, M.B., B.S. Lond., of New Milton, Hants, to Mary, only daughter of Mr. and Mrs. E. Jump, of Cambridge-road, Wimbledon.

SMITH—HOOGEWERF.—On Sept. 28th, at St. Mary's Church, Egerton-gardens, N.W., Kenneth Shirley Smith, M.D., M.R.C.P., to Alice Wilhelmina, elder daughter of Mr. and Mrs. Edmund Hoogewerf, late of Industries Department, Bengal.

DEATHS.

BOND.—On Sept. 24th, at a nursing home, Eastbourne, Charles Knox Bond, M.D.

FRASER.—On Sept. 26th, Dr. Mathew William Fraser, Rimpton, Somerset, and late of the West African Medical Service.

GLYNN.—On Sept. 22nd, Ernest Edward Glynn, M.D., F.R.C.P., late Professor of Pathology, University of Liverpool, aged 56.

MITCHELL.—On Sept. 27th, at Aberdeen, Peter Mitchell, M.D., C.M., aged 65 years.

SMYTH.—On Sept. 23rd, at St. Ives, Cornwall, William Ardagh Smyth, L.R.C.P., L.R.C.S. Edin.

N.B.—A fee of 7s. 6d is charged for the insertion of Notices of Births, Marriages, and Deaths.

PRINCE OF WALES'S GENERAL HOSPITAL.—This institution at Tottenham is the only large London general hospital which serves a population of three-quarters of a million in the industrial district of north-east London. There are 200 beds, and the report for last year shows that 2796 patients were dealt with, and that their cost, for an average stay of 22 days, was £10 17*s.* 7*d.* New out-patients numbered 28,780 and cost 8*s.* 3*d.* each. The antiquated out-patient department urgently needs to be rebuilt, which would cost £35,000, of which only one-seventh is yet in hand.

BIRMINGHAM CRIPPLES HOSPITAL.—The annual report describes the additions that are being made to the Woodlands Hospital which are to be opened by the Duke and Duchess of York at the beginning of November. There is a new children's ward divided into two sections, one for boys and the other for girls, with 30 beds in each; adult male and female wards each have 20 beds. A nurses' home will accommodate 41 probationers and 8 sisters, and new theatre and massage departments have been provided. In 24 years the Workmen's Auxiliary Committee has given £28,000 to the hospital.

Notes, Comments, and Abstracts.

OBSERVATIONS IN ICELAND.

HISTORY AND HEALTH.

(FROM A SPECIAL CORRESPONDENT.)

IN the summer of 1929 I visited Iceland with a view to getting into touch with the members of the Icelandic Red Cross, studying its work, and ascertaining if there were any ways in which the League of Red Cross Societies, of which the Icelandic Red Cross Society became a member in 1924, could be of service to it. Before undertaking this study visit, I called on Dr. Gregg, of the Rockefeller Foundation in Paris, as he had recently visited Iceland on behalf of the Foundation. The information he most generously put at my disposal provided me with a very useful bird's-eye view of the whole situation, and I started on my journey not only infected with some of his enthusiasm for what he called "a beautiful little rock garden" in the Atlantic, but also grounded in some of the elements of the public health problems of Iceland.

To those who may feel tempted to visit Iceland (and I recommend it as a most curiously fascinating country, calculated to titillate the palate of the most jaded globe-trotter) I would mention the very comfortable route I followed—a special boat-train from King's Cross to Newcastle, a boat that takes only 24 hours to Bergen, and the *Lyra*, which leaves Bergen every other Thursday, and reaches Reykjavik early the following Tuesday, after having touched at the Faroe Islands. The Bergenske Dampskibsselskab, on whose boats I travelled, charge 210 kroner for this journey from Newcastle to Reykjavik, board being included in this first-class ticket. The exchange value of the Norwegian krone is about 18 to the pound sterling.

The visitor to Iceland who intends to do something more than play bridge on board ship and take snapshots of his fellow travellers and other bizarre objects, would do well to study the outlines of its history. It was the last of all the European countries to be colonised, the first colonists settling in A.D. 874. The settlers were chiefly Norwegians, many of them being of noble birth and of too independent a spirit to submit to the rule of Harald Haarfagre, King of Norway. In his interesting anthropological study of Iceland, Prof. Gudmund Hannesson has drawn attention to the influence this process of selection has had on the physique of the Icelander of to-day. He has found that the modern Icelander is taller than his contemporaries in the parent Scandinavian countries, and he assumes that the first settlers were as a class tall men, as well as being chieftains of noble blood. Most of the present-day Icelanders can trace their descent uninterruptedly from one or other of these chieftains, and it is this fact which largely explains the spirit of chivalry and old-world courtesy which permeates all classes. The modern Icelander is something of the *grand seigneur* whose instinctive, but unwritten motto is: *noblesse oblige.* The visitor would do well to remember that the hospitality he receives on some lone farm is not that of some humble crofter, but of a nobleman whose ancestors would have regarded most of the folk who "came over with the Conqueror" as parvenu adventurers.

The first 60 years of the history of Iceland were politically nondescript. In 930 the country became a republic, with an Althing, or Parliament, and a code of laws for the whole country. It was a free and sovereign State which lost its independence in 1262, when it came under the rule of Norway. In 1380 its allegiance was transferred to Denmark, and under Denmark it remained till only a few years ago. In 1918, after many years of difficult negotiations with Denmark, Iceland achieved independence, and it is now a sovereign State again. As an independent monarchy, it is reigned over by the King of Denmark. Next year, on June 26th, 27th, and 28th, Iceland will celebrate at Tingvalla, the volcanically-formed, open-air forum a few miles outside Reykjavik, the thousand-year jubilee of parliamentary government.

The total area of Iceland is 103,000 square kilometres, but the habitable area is small and is chiefly limited to the coast and certain valleys. At Reykjavik the annual mean temperature is 4·1° C., the mean temperature in January, which is the coldest month of the year, being 1·2° C. The mean temperature in July, which is the warmest month of the year, is 10·0° C. Iceland is generally reputed to be very bleak and fog-bound, but in the summer, at any rate, there is plenty of sun, and a solarium in the new hospital at Reykjavik is a tacit protest in concrete against this reputation. A few miles outside Reykjavik there are conservatories, heated by natural hot springs, in which tomatoes and melons ripen.

The population of Iceland on Dec. 31st, 1927, was 103,317, that of Reykjavik alone being 21,301. This nation is rapidly growing, the population on Dec. 31st, 1925, being only 100,117. The birth-rate in 1927 was 25·0 per 1000, and the death-rate 12·4. In the past, much of Iceland's surplus population has emigrated, and there are approximately 25,000 in Canada and the United States alone. At the present time Iceland can absorb her own surplus population, chiefly because the modern development of her fisheries is bringing her unprecedented prosperity. It is for this reason that the increase in the population concerns only the coastal areas. But though the rural population has stood still, or even dwindled, it is only a matter of time, probably quite a short time, before the rapidly growing network of roads and the exploitation of Iceland's superabundance of water-power, will people the interior with many times its present population. At present, with almost four-fifths of the country uninhabited, and for the most part uninhabitable on account of glaciers, volcanic deserts, &c., there is something less than one person per square kilometre. The excess of females above males reflects to a certain extent the increased hazards of drowning to which males are disproportionately subjected. In the five-year period 1916–20 almost two-thirds of the deaths from accidents were due to drowning. Many doctors lose their lives in this way; crossing a swollen torrent, the doctor is carried away, while his pony swims ashore.

There are about 100 doctors in Iceland (in 1927 there were 98), 48 of whom act as medical officers of health in as many administrative medical districts. They are, of course, general practitioners as well. In almost every parish there is a trained midwife, and the total number of trained midwives is about 200. Their duties include vaccination, which has been compulsory since 1810. But there are only about half a score of dentists and as many chemists in the whole of Iceland. A medical director is responsible for the administration of all matters concerning public health.

Housing and Town-planning.

Some thousand years ago the dwelling-houses were comparatively large, and the birch wood which then covered the island provided plenty of fuel for the fires burnt in the middle of the room in the old Norwegian fashion. Later, lack of timber for building purposes and of wood for firing compelled the inhabitants to live in small huts of turf and rough stones, providing only some 5 cubic metres for each person. As Prof. Hannesson puts it: "The birch wood forests disappeared. . . . There was no coal, and good peat was scarce. The fire of the hearth was no longer lit. For centuries the Icelanders have lived in almost unheated houses. . . ." This state of affairs is changing, as a rule for the better. But in the rapidly growing villages and towns on the coast there is a serious housing shortage, and the dwellings are apt to be poor as well as overcrowded. The new buildings are usually made of concrete. The double outer walls are provided with an intermediate space which is packed with dry peat dust or chips of cork. These houses are both warm and fire-proof. Central heating is sometimes provided by natural hot springs, and electric light from some neighbouring waterfall. Recent town-planning legislation obliges all communities numbering 500 and upwards to make a survey of the harbour and of as much of the surrounding land as will be required for the growth of the community in the next 50 years. The cost of this survey is borne equally by the Government and the town. All communities having a Government-ratified town plan are subject to Government inspection every fifth year, and all new buildings which do not conform to the town plan are to be immediately pulled down at the cost of the town. This legislation is said to have worked satisfactorily on the whole.

Infant Welfare.

Few figures are so eloquently demonstrative of the progress made during the last decades as those dealing with vital statistics. During the period 1886–95 there were 86 still-births for every 1000 births. During the five-year period 1916–20 this figure was reduced to 29, and during the five-year period 1921–25 there was a further reduction to 25. According to the reports of midwives, 95·4 per cent. of the infants in Reykjavik, and 75·8 per cent. in the country districts, were breast-fed. The average infant mortality of 52·8 per 1000 in the five-year period 1921–25 is among the lowest, if not the lowest, in Europe.

Tuberculosis.

Until the last quarter of the nineteenth century, when housing and sanitation were at a low level and semi-starvation not rare in Iceland, tuberculosis was hardly known. During the last decades, housing, general sanitation, and the nation's diet and standards of cleanliness have vastly improved. Preventive and therapeutic measures in relation to tuberculosis have absorbed increasingly large sums of money. Yet the disease has apparently increased by leaps and bounds. In 1921 the number of notified cases was 746, whereas in 1927 this number had risen to 1100. The rise in the death-rate from tuberculosis was much less abrupt. In the five-year period 1911–15, with an annual average of 147 deaths, it was 1·7 per 1000, whereas in the five-year period 1921–25, with an annual average of 186 deaths, it was 1·9 per 1000. The apparent rarity of tuberculosis in former years may partly be traced to defective diagnosis and notification, but it would also seem that the improvement of communications, and all that this improvement entails, have favoured an actual increase of the disease. This increase has been spread over several decades, and may not yet have reached its maximum. The first sanatorium (Vifilsstadir Sanatorium, 140 beds) was not built till 1910.

Drastic and costly measures have been taken to combat tuberculosis. In 1921 a special law was passed, and strict regulations were adopted with regard to notification and the prevention of infection. Disinfection is compulsory when a patient moves or dies, his home cannot be used as a school, and children with open tuberculosis may not attend ordinary schools. The subjects of open tuberculosis may not be employed as school teachers or midwives, nor work in milk shops, restaurants, or provision stores. Children and young persons may not live in the homes of patients suffering from open tuberculosis. The State not only provides sanatoriums and similar institutions, but also defrays three-fifths of the running expenses, except when the patients are in easy circumstances. In practice nearly all open cases are given free treatment for a long period in sanatoriums and hospitals, and the annual cost to the State now exceeds 500,000 kr. Of all the cases notified in 1920, 27·7 per cent. were under the age of 15. Of the patients over this age and suffering from pulmonary tuberculosis 64·5 per cent. were women—a curious sex disproportion which is the more remarkable as only 51·2 per cent. of the patients suffering from tuberculosis of organs other than the lungs were women. About 20 per cent. of the deaths from tuberculosis in 1926 were due to meningitis.

Tuberculosis is rare in cattle; measures have recently been taken against it. In 1923 it was made notifiable. Diseased animals must be inspected by a veterinary surgeon and slaughtered if necessary, the cost of these measures being borne partly by the State, partly by the local authorities.

Leprosy.

Leprosy was formerly very rife in the country, and as late as 1896 there were as many as 280 lepers. In 18[illegible] a 60-bed hospital for lepers was built near Reykjavik. By 1921 the total number of lepers had fallen to 63, and in 1927 this number had been further reduced to 44, 31 of these patients being resident in the hospital. Four new cases were notified in the five-year period 1921–25.

Venereal Disease.

Gonorrhœa became endemic in Iceland about 1800, and syphilis after 1900. As was to be expected, these diseases are practically limited to the seaports, and a considerable proportion of the patients are foreigners. Gonorrhœa and syphilis are increasing. Legislation in 1923 provided for the compulsory notification and treatment of cases of venereal disease, the cost of residence and treatment in hospital being free for persons in necessitous circumstances. The medical officers of health are instructed to conduct educational campaigns against this disease in those areas where it is rife. Persons suffering from venereal disease in an infectious stage are forbidden by law to marry. In 1927 there were 318 cases of gonorrhœa notified, the annual average for the five-year period 1921–25 being 230. As many as 12 of the 31 patients notified as suffering from syphilis in 1927 were foreigners. The annual average of notifications of syphilis in 1921–25 was 25.

Influenza.

There is a deep-rooted conviction in Iceland, both with regard to man and to cattle, that the plagues from which the country has suffered from time to time have been imported from abroad. Doubtless this conviction is well founded. But in the case of cattle, at any rate, it has done much to prevent the improvement of the stock by new and better imported strains. Influenza is no exception to the rule that most infectious diseases are imported, all the serious outbreaks being traced to infection from abroad. The "Spanish influenza" of 1918 caused many deaths, but also conferred an immunity in the survivors which was little impaired when another epidemic wave invaded the country in 1921. This epidemic lasted for five months, reaching its maximum in the third month. Three districts escaped completely by voluntary isolation, and there were many instances of whole parishes and single farms escaping the epidemic by this means. The epidemic of 1924 lasted for some months, reaching its maximum in the second month. In some districts it spread to almost every home, while in other districts it was much more sporadic as a result of preventive measures or of the immunity left by the waves of 1918 and 1921. The comparatively slow spread of the disease in most districts may have been due in great part to this immunity. The death-rate from the epidemic in 1924 was about 1 per cent. The growing immunity to influenza seems to have created a crop of abortive cases and to have rendered the differential diagnosis of influenza and acute bronchial catarrh very difficult. The latter disease did not spread so rapidly, and the one disease did not confer immunity to the other. Cases of influenza were most infectious in the latter half of the incubation period, and shortly after the outbreak of symptoms, but usually for not more than four days after this outbreak. The age-incidence varied in different epidemics, in some of which few persons under the age of 15 suffered, whereas in others there were many patients under this age. While only 941 cases were notified in 1925 the number of notifications rose to 3115 in 1926, in the latter half of which there was a typical epidemic which spread rather slowly. Most of the persons who had had influenza in 1925 were immune, but in isolated areas, which had not been visited by influenza for some years, the epidemic spread to almost every home and caused considerable havoc.

Epidemic Pleurisy.

In 1911 and again in 1917 there were small outbreaks of this obscure disease. An epidemic in 1923 was investigated by the bacteriologists Dr. Thjötta and Dr. Salvesen, but no specific germs could be found. A serious outbreak occurred in 1926. It began in Reykjavik in June, and it was not clear whether it was imported from abroad or not. The 87 notifications in Reykjavik in June rose to 148 in July and sank to 42 in August, petering out soon afterwards. In the latter half of the year it spread to about 20 districts. The main epidemic ran through the country in four months, reaching its maximum in the second month. The incubation period was short, and the disease began with high fever, sometimes of a remittent character, associated with more or less violent pain in the chest. Sometimes this pain was like that of pleurisy or lobar pneumonia, sometimes it was more diffuse, involving the upper abdomen as well as the lower part of the thorax. The pain was often so severe and the abdominal muscles were so tender that the patients preferred to lie motionless. The stethoscopic examination was sometimes negative but sometimes revealed definite pleuritic rubs over the lower parts of the lungs after the patient had been ill for some days. The illness lasted a week or a week and a half, usually without any signs of bronchial catarrh or influenza. Relapses occurred, notably after exertion or exposure, but no case ended fatally. While the rapid spread of this epidemic over a great part of the country has caused it to be regarded as a modified form of influenza, the facts that it has formerly occurred in small local epidemics, and that its manifestations are in many respects different from those of influenza, are opposed to this conception. Outbreaks of this disease in the middle of the winter weaken the case for regarding it as insect-borne.

Rheumatism.

The number of cases of acute rheumatism observed every year does not vary greatly, nor is there any marked seasonal difference. The disease seldom runs parallel with acute tonsillitis, scarlet fever, or diphtheria. It is usually of a mild type, and not only is it less frequent than in neighbouring countries but it is also comparatively seldom followed by endocarditis. Salicylates have but a slight effect on it, and it is possible that it is often of tuberculous origin (Poncet's rheumatism). The proportion of male to female patients is as 1 to 3. Among the 146 cases of acute rheumatism notified in 1926 there was not one in which heart complications were mentioned.

Lobar Pneumonia.

This disease is frequent in Iceland and its incidence varies greatly from year to year. Thus, in the five-year period 1916–20, the annual notifications averaged 812, whereas in the five-year period 1920–25 this figure rose to 913 cases. In 1926 only 185 cases were notified, whereas in 1925 there were 278 cases. The disease was most frequent in the North and West, and in the months of May and June. The age- and sex-distribution showed some curious features. In over 10 per cent. the patients were under the age of 15. Between the ages of 15 and 65 the percentage-incidence was 52·4 for males and 22 for females. Over the age of 65 this preponderance among males was continued, the respective percentages being 4 and 2·4. In some cases the disease was very contagious, and on one farm all the five inmates were ill at the same time.

Measles.

An epidemic of measles, imported from Norway in 1924, ran through the country and lasted till 1926. Public measures taken in the beginning of the epidemic failed to arrest it, but voluntary isolation was temporarily effective in many districts. It ran on the whole a mild course, with a mortality of about 0·5 per cent. In earlier years, and before the inhabitants had become immunised, the epidemics which swept over the country at long intervals were associated with a high mortality. This epidemic seemed to have come to an end in October, 1925, but in November there was a recrudescence of it, the peak being reached in January, 1926. It died out in August of this year. While the usual duration of epidemics of measles is 14 to 16 months, this epidemic lasted about 26 months—a spell the length of which may be traced to the preventive measures which were adopted in certain districts, and which evidently deferred without permanently aborting the evil. The districts which entirely escaped this epidemic may find measles a very unpleasant rod in pickle when the next epidemic invades the country. Prevention of the disease by the injection of the serum of convalescents was found effective in some districts.

Hydatid Disease.

Some 60 or 70 years ago hydatid disease of the liver caused by *Tænia echinococcus* was so common that about 2 per cent. of the inhabitants were supposed to suffer from it. Now this disease is becoming rare, thanks to the drastic measures taken against it. About 25 years ago Dr. Steingrimur Matthiasson, now in charge of the hospital in Akuryri, the second largest town in Iceland, found that operations for hydatids were the most frequent of all major operations at his hospital, whereas at the present time he can count such operations on the fingers of one hand in the course of the year. In 1863 there was one dog to every three to five inhabitants, whereas at the present time this dog-to-man ratio has been reduced to 1 to 16. Thanks to the energetic efforts of Dr. Gunnlaugur Claessen and his colleagues, no one may keep dogs in Reykjavik, and in certain other communities they are excluded or kept under very close control. The law of 1890 imposed a tax of 2*s.* to 10*s.* on every dog, and enjoined the deep burial or burning of hydatid-infected material found in slaughtered animals. The same law imposed on all town and parish councils the task of purging dogs with areca powder after the slaughtering time in the autumn. Dr. Claessen's recently published work on X ray aspects of hydatid disease, qualifying him for the degree of M.D. in Sweden, promises not only to be a standard work in this field, but is also a good example of the scientific activities of the medical profession of Iceland to-day.

(To be concluded.)

ASPIRIN AS A HIRUDICIDE.

To the Editor of THE LANCET.

SIR,—During the Great War in a district in Palestine where no doctors were easily available, a woman with a sick child who suffered from fever and spitting of blood consulted a pharmacist. The puzzled man invoked his old friend aspirin to combat the fever. An hour after having administered aspirin to the boy the mother returned with two big leeches in her hand, thanking the pharmacist and reporting the cure of the child. Henceforth we made experiments on dogs afflicted with leeches by simply throwing aspirin into their mouths, and in all cases this treatment has proved effective. I believe aspirin is a much better treatment for leeches than the extraction method.

I am, Sir, yours faithfully,
BUTRUS SALAH, M.D.

Jaffa, Palestine, Sept. 18th, 1929.

THE DESTRUCTION OF HOME PESTS.

ALL households, especially those situated in the country, are at some time visited by one if not more of the ordinary home pests such as ants, flies, or mosquitoes. Since these are a menace to public health it is important that everyone should be familiarised with the best methods of exterminating them. A brief knowledge of their habits and life histories is essential if these pests are to be intelligently combated. Since it is easier to cope with them in the egg or larval stages than after they have become adults, Mr. J. S. Bainbridge[1] recounts the habits, life-histories, and tested methods of control of all the common household pests, gives simple practical advice, and includes a number of clear illustrations.

An Address

ON

RECENT AIDS IN THE DIAGNOSIS OF SOME COMMON DISORDERS.

Delivered at the St. Mary's Hospital Post-graduate Course on Oct. 4th

BY T. C. HUNT, B.M. OXF., M.R.C.P. LOND.,
MEDICAL REGISTRAR OF THE HOSPITAL.

HIGH BLOOD PRESSURE.

THE diagnosis of high blood pressure is, of course, easy, and difficulty only arises when its significance has to be estimated.

The upper limit for the normal constant systolic pressure should never, whatever the age of the patient, be above 155 mm. of mercury. This figure is rather lower than used to be accepted, but is probably too high rather than too low. For the diastolic pressure a figure over 95 mm. is always to be considered as abnormal. There is no doubt, however, that remarkable temporary variations in systolic blood pressure may occur, especially under the stress of emotion, fear during examination, and the like, and it is common to find the first reading taken with the sphygmomanometer to be 10, 20, or even 30 mm. higher than subsequent readings.

In this connexion there is one important variation which can often be detected by the sphygmomanometer although the finger may do no more than suspect it. This is the pulsus alternans, which is particularly apt to be found in cases of high blood pressure and is shown by a doubling of the number of beats heard or felt below the arm-band, as the pressure is gradually lowered from the point at which the first sounds appear. The difference between the systolic pressures of alternate beats may be as much as 10 or even 15 mm. of mercury, and such a finding is always of the gravest importance.

The diastolic pressure, which is at least as important as the systolic, shows less variation and should always be recorded with the systolic.

When a persistently raised blood pressure is found it may be hard to determine to what extent (if any) it is associated with definite involvement of the kidney. The exact height of the pressure is no indication of the presence or degree of renal damage. Nor is peripheral arterio-sclerosis by any means constantly present; indeed the hard tortuous arteries so commonly found, for example, in manual labourers are often to be seen in cases where the blood pressure is not raised at all.

Hypertension occurs in practice essentially in three forms: (*a*) as a condition sui generis without changes in the kidney; (*b*) associated with renal arterio-sclerosis (nephrosclerosis arterio-sclerotica); and (*c*) associated with, and probably secondary to, granular contracted kidney of the true inflammatory type. The first of these is called essential hypertension or hyperpiesia; the two latter forms we group together clinically as chronic interstitial nephritis. There are, however, important distinctions between the two members of this group, and since the prognosis is largely dependent upon their separation I propose to say something firstly about a few points in this differentiation, and secondly and more particularly about the early recognition of renal damage of whichever type it may be.

Arterio-sclerotic Kidney.

Briefly stated, high blood pressure associated with arterio-sclerotic kidneys presents the following features. The systolic blood pressure is subject to fairly wide variations under different circumstances, and may fall considerably with rest in bed. The diastolic pressure is apt to be relatively low, and thus the range between systolic and diastolic is high—i.e., the pulse pressure may be 120 mm. or even more. The patients are most usually elderly, often 60 or over, and frequently nervous and excitable about themselves; their colour is good—that is to say, there is no anæmia. The retinæ show arterio-sclerotic changes, pinching of the veins, and silver-wire arteries, and sometimes hæmorrhages. The prognosis, with suitable treatment, is comparatively good and the cause of death is apt to be apoplexy or heart failure.

Secondarily Contracted Kidney.

The second type, in which the high blood pressure is apparently the result of primary nephritis, corresponds to the true "small white kidney" which follows a recognised or unrecognised acute nephritis. Here the systolic blood-pressure is usually far more fixed and seldom varies more than 10 or 15 mm. though it tends to rise somewhat during the course of the day; it is not necessarily very high, but the diastolic pressure is, in comparison, often much raised. The patient is generally younger, perhaps 30 or 40 years of age, and is markedly anæmic. The anæmia is, indeed, such a striking feature that these cases are often described as white hypertension, in contrast to the former type which is called red hypertension. The anæmia is probably the result of a chronic toxæmia, and is so important in prognosis that it is probably correct to say that when the red cell count is 3 million or under the patient will not live longer than two years. In these cases death is commonly from uræmia and the prognosis is bad.

A Differential Test.

In the early stages both these types of patient present themselves, as a rule, as simple cases of high blood pressure, with or without symptoms attributable to this. Of the various symptoms I would mention especially "rheumatic" pains in the limbs, headache (especially occipital), vertigo (sometimes), and dyspepsia (often). Dyspnœa on exertion is particularly common in the arterio-sclerotic type, as also are "rheumatic" pains, whilst headache is especially frequent in the inflammatory type. The early symptoms, however, rarely indicate the extent or nature of the renal damage; polyuria may not be complained of and in both types the urine may not be characteristic in its content of albumin, blood, or casts—all of which may indeed be absent.

It is in the diagnosis of the presence, degree, and to some extent of the type of nephritis in cases of this kind that I would like to call attention to one simple test which, though in no sense new, is yet recent in its application. I refer to the water test of kidney function of F. Volhard and Koranyi. This test is in routine use in almost all continental clinics, and widely in America, and I think it deserves more general recognition in this country. Thanks to the kindness of Prof. F. Langmead I have had the opportunity of applying it on many patients in the wards, and I feel that in such cases as I am discussing its simplicity and usefulness make it of very great value. The test, as I apply it, is as follows.

The patient is instructed to take as little fluid as possible from lunch-time onward, but to eat his ordinary diet; no fluids at all are drunk after 6 P.M. when the bladder is emptied (and the urine discarded). All the urine passed from this hour until 9 A.M. is then collected and measured, and a specimen is saved. At 9 A.M. a pint and a half of weak tea or water is drunk, and the urine is passed hourly for at least four, and if possible six, hours; each hourly specimen is measured and a sample is saved. The test can easily be carried out at home, preferably perhaps over a Saturday and Sunday, and if the hourly collection of specimens is difficult almost as much information may be obtained by examination of two-hourly samples. The specimens are all investigated as regards their volume and specific gravity.

The patient should be in bed during the test, for otherwise extrarenal factors—especially cardiac—are involved which lessen the value of the results. Such conditions as obvious heart failure, gross œdema, or severe diarrhœa, must naturally also vitiate the test, though they will not often be encountered in the type of patient that I am discussing. It is advisable, further, to carry out the test on one or two separate occasions if possible rather than to rely entirely upon one examination.

Night Urine.—The normal patient should not excrete more than about 20 oz. of urine during the night period, and the specific gravity should not be less than 1025. *The restriction of fluids before going* to bed ensures a maximum concentration in this specimen which *normally* bears *a ratio to the day* urine of about 1 to 3. The average volume in health *is less than 15 oz., and the average specific gravity* 1032 (T. Addis and M. C. Shevsky).

Water Test or Dilution Urine.—All the 30 oz. of fluid drunk in the morning should be excreted within 4½ to 5 hours; *it is usually put out in not more than* four. More than half—i.e., 15 oz.—should be excreted *in the first two hours,* and the rate of removal of the test dose is of great importance. The maximum flow should be during the second hour of the test, when the volume should not be less than 10 to 15 oz.; the flow at its maximum point reaches a rate of nearly half an ounce a minute (E. B. Verney); the specific gravity should fall to 1003 or lower. These figures have been obtained over a large series of normal subjects, and may be taken as substantially correct.

Results of the Water Test in Cases of High Blood Pressure.—All are agreed that the earliest evidence of renal impairment is shown by a poor concentration of the night urine. This is especially true of the inflammatory group of cases, in the early stages of which the volume is high (greater than a pint and often two or three pints), and the specific gravity is low. In the arterio-sclerotic kidney these changes are less marked; here the volume at night is slightly increased but the specific gravity is less reduced. Thus, for example, the volume may be 25 oz. and the specific gravity 1018, whilst in the inflammatory kidney the volume may be 40 oz. and the specific gravity 1006. In the *late* stages of both conditions the nocturnal polyuria ceases—a sign, as it were, of "decompensation" of the kidney—but the specific gravity remains fixed at 1010. Thus a small night volume with a specific gravity not greater than 1012 suggests a very serious prognosis.

The output of the test dose is also an excellent guide to the extent of renal damage. In the very lightest degrees there may be an excessive output, so that an abnormally high volume may be passed in four hours—well above the 30 oz. originally given. But the significance of this is somewhat doubtful, and in general it may be said that the less the amount put out of the 30 oz. given the worse the prognosis; the more the specific gravity remains fixed at 1010, the smaller each hourly volume becomes, and the more each equals another in volume the more grave is the impairment. Equality in volume of the consecutive specimens is a sign of serious import but indicates less severe impairment than does great diminution in the hourly amounts.

To some extent the response to the test may, I think, differentiate the nature of the lesion. Thus the inflammatory kidney which acts normally at its maximal excreting power shows a constant polyuria (by day and especially by night) but fails to excrete the added dose of fluid. A typical result is the following, the patient being a man of 55 who was sent home from abroad as a case of peripheral neuritis, with a blood pressure 220 systolic and 135 diastolic.

Hour.	Volume.	Sp. gr.
1st	1¼ oz.	1011
2nd	1 ,, ...	1010
3rd	2 ,, ...	1010
4th	1¼ oz.	1011
5th	2 ,, ...	1010

Total excretion in 5 hours—of 30 oz. given—8 oz.

This patient showed a maximum urea concentration of 2·1 per cent. and a blood-urea of 60 mg. per cent., and died six weeks later from uræmia—an outcome which might not have been expected from the results of the urea-concentration test or blood examination alone.

The arterio-sclerotic kidney retains more of its power of excreting water, and most of the fluid given is excreted within six hours; the specific gravity is also lower and may fall in the largest specimen to 1005 or under. The following are two further examples of actual results which I think will demonstrate the value of the test.

A patient, aged 68, of high colour, had some arterio-sclerosis of the peripheral vessels. The blood pressure was 180/125, and there was a history of transitory left-sided hemiplegia. The maximum concentration of urea in the urine *after 15 g. of urea* was 3 per cent., but the minimum was down to 1·2, so that a range of 1·8 was found, which did not suggest any nitrogen retention in the blood; the blood-urea was in fact 20 mg. per 100 c.cm. There was slight albuminuria but no casts were found. The water test gave the following figures:—

Night urine.—Specific gravity 1015. Volume 23 oz.

Hourly specimens after 30 oz. of fluid—

Hour.	Volume.	Sp. gr.
1st	No urine ..	—
2nd	8 oz.	1014
3rd	4 ,, ...	1008
4th	4 ,, ...	1007
5th	1 oz.	1006
6th	2 ,, ...	1012
7th	2 ,, ...	1014

In this case there is a delay with a moderate retention (11 oz.) at six hours; the specific gravity falls to 1006, giving a total range of 9. There is thus a definite picture of moderate arterio-sclerotic nephritis.

The second case, in contrast to the above, is that of a woman, aged 55, with some traces of albumin in the urine and a blood pressure of 175/110. The urea concentration was 4·2 per cent. after 15 g. of urea and in the dilute specimen 0·25 per cent.—i.e., there was a range of 3·95. The night urine showed a specific gravity of 1019 and volume 14 oz. The blood-urea was 26 mg. per 100 c.cm. The water test showed:—

Hour.	Volume.	Sp. gr.
1st	5 oz.	1010
2nd	23 ,, ...	1003
3rd	5 oz.	1008
4th	2 ,, ...	1012

Here the total volume of fluid is fully excreted in four hours and the range of specific gravity is high from 1019 to 1003—i.e., 16. This was therefore clearly a case in which a serious renal involvement could be confidently excluded, the only suspicious features being a slight failure of specific gravity in the night specimen and a somewhat excessive output of fluid in the second hour, with a total excretion just above the test quantity given. It will be seen that the volume and specific gravity tests alone were able to eliminate with some certainty any marked degree of arterio-sclerotic nephritis.

The main value of the test lies in estimating the extent of renal damage and is of the greatest value in prognosis. Thus if the specific gravity does not vary appreciably from 1010, and not more than half the test dose is excreted in six hours, the patient is unlikely to live more than a few months. To sum up, I will repeat the main points in estimating the degree of renal impairment.

Early Stages.—(1) A night urine of volume greater than 20 oz. and specific gravity below 1020. (2) Delayed and incomplete excretion of the test dose of water.

Later Stages.—(3) An increasingly smaller difference between maximum and minimum specific gravities, with a night urine of less volume but specific gravity approximately 1010; an equality in volume of the specimens following the fluid, the quantity of each being not more than 2 or 3 oz. (4) Fixation of specific gravity in all specimens at between 1009 and 1012.

In the attempt to differentiate early arterio-sclerotic from early inflammatory cases, we may say that, broadly speaking, the inflammatory kidney shows a greater polyuria, especially nocturnal, a greater fixation of specific gravity, and a greater inability to excrete a test dose of fluid. The arterio-sclerotic kidney shows a more normal daily urine volume, less nocturnal secretion, a higher range of specific gravity between concentrated and dilute specimens, and better power of excreting an excess of fluids.

Nitrogen Retention.

It may be that these distinctions are largely those of the severity of the renal impairment, but in accurate diagnosis and prognosis they are of real importance. They are of especial value in cases of high blood pressure with early kidney damage such as I am discussing, since albuminuria may be slight or absent and a raised blood-urea is a late occurrence.

Further in this stage the urea-concentration test—as usually carried out—may not show any renal defect. Thus in both arterio-sclerotic and inflammatory nephritis the maximum urea concentration in the urine after a dose of 15 g. of urea may be 2 per cent. or over—i.e., within normal limits. If, however, the dilute specimens after the dose of fluid are examined the contracted kidney may show a concentration of 1·9 per cent., or even an unaltered percentage, whilst the arterio-sclerotic kidney shows a figure of, say, 1 per cent. or even less. In this way, as was suggested by Dr. E. G. B. Calvert, estimation of the urea in the night specimen and in the dilute specimen after the fluid will provide a range of urea-concentration test, which gives similar information to the range of specific gravity but is less simple of application.

There is one further point in this connexion—namely, the detection of the presence of nitrogen retention in the blood. Even in uræmia there is not *always* a raised blood-urea, but it is a laboratory finding of great importance. A high blood-urea may be generally inferred when the specific gravity range is less than 3, and the maximum figure about 1010, whilst if the specific gravity in any specimen falls below 1006 it is unlikely to be present. In terms of urea concentration, if the maximum concentration is 2 per cent. or less, and the minimum is not lower than 0·2 to 0·3 per cent. less, the blood-urea is almost sure to be raised. A rough check upon the blood itself is easily available, without recourse to exact laboratory methods, in a simple test devised by Weltmann. This requires the use of two reagents only and is performed as follows:—

Five c.cm. of blood are taken from a vein and an approximately equal volume of trichloracetic acid is added to it at once. The mixture is then shaken and filtered. To the clear filtrate 5 drops of Ehrlich's aldehyde are added—a reagent to which I shall refer later. If the blood-urea is raised above about 40 mg. per cent., which is the upper normal figure, a greeny-yellow colour develops, which is darker and more intense the higher the blood-urea. If no colour develops any appreciable degree of nitrogen retention can be confidently excluded.

This test is simple, sufficiently accurate, and of real value—for example, in cases of coma when uræmia is suspected as the cause.

Types of High Blood Pressure with Early Renal Involvement.

Arterio-sclerotic.	*Inflammatory.*
Age.—Over 40.	Often under 40.
History.—Previous good health.	Previous acute nephritis; often chronic focal sepsis.
Appearance.—Red; excitable.	Pale; lethargic.
Main symptoms.—Dyspnœa; rheumatic pains; angina pectoris.	Headache; dyspepsia; often polyuria.
Blood pressure.—Variable.	Fixed.
Blood.—Sometimes plethora or polycythæmia.	Anæmia.
Ocular changes.—Silver-wire arteries; pinching of veins; hæmorrhages. Later sometimes "fluffy" patches of exudate.	Similar, but with fan-shaped exudate round macula.
Urine.—Albumin, blood, and casts may be present or absent in either type.	
Night urine.—Volume about 20 oz. (max. concentration). Specific gravity about 1018.	Volume more than 20 oz. Specific gravity 1015 or less.
Max. urea concentration.—Approx. 2% or more.	Approx. 2% or less.
Min. urea concentration.—Approx. 1% or less.	Approx. 2%.
Urea range.—Approx. 1% or more.	Approx. 0·2% or less.
Water test.—Good dilution; delay in output, but little retention over 6 hours.	Bad dilution; volumes of specimens small; equal half or less of the fluid excreted in 6 hours.
Specific gravity range.—Fairly good—e.g., 1018 to 1005.	Relatively fixed—e.g., 1015 to 1008.
Blood-urea.—Not raised till late.	Often raised early.
Duration.—Often many years.	Short—1 to 4 years.
Outcome.—Apoplexy; cardiac failure; angina pectoris.	Uræmia: intercurrent disease; heart failure.

Further Guides to the Condition of the Kidney.

The above table shows very schematically the main features which may help in differentiating the early stages of arterio-sclerotic from those of inflammatory kidney; it must not be taken as in any sense a hard-and-fast classification, and is merely meant as a rough guide to which there must be many exceptions. It must be remembered, moreover, that it is possible that these types may be but different stages of one and the same disease, which is probably primarily a vascular one. Nevertheless definite pathological differences can be found post mortem, and in practice the distinction is not an unimportant one. For a full discussion of this point I would refer the reader to Dr. T. Izod Bennett's Goulstonian lectures of 1928.[1]

DIAGNOSTIC SIGNIFICANCE OF THE PRESENCE OF UROBILIN IN THE URINE.

Urobilin is a biliary derivative which may sometimes appear in the urine and is quite distinct from the true bile-pigments, bilirubin and biliverdin, which are present in the blood and urine in such conditions as obstructive jaundice, and are detected in the urine by the formation of a green ring with either strong nitric acid or (better) a dilute solution of iodine in potassium iodide. Under the term urobilin I include both this substance itself and its probable precursor, urobilinogen, since their occurrence and importance are clinically the same.

The mode of formation of urobilin is as follows. The bile-pigments, bilirubin and biliverdin, are formed from the hæmoglobin of the blood, secreted in the bile by the liver, and reach the intestine through the common bile-duct. In the intestine they undergo a change into urobilin (probably through bacterial action), some of which appears in the stools under the name of stercobilin. Most of it, however, is absorbed back into the blood, reaches the liver again, and is then reconverted into bilirubin. So a circulation of the bile-pigments takes place.

Clearly an excess of urobilin may be present in the blood for two main reasons: (1) an excess of pigments may be formed originally from the blood so that an excess will reach the intestine and thus an excess of urobilin will be absorbed from the gut. (2) The liver may fail to reconvert the normal amount of urobilin which reaches it after absorption from the intestine. This liver function of converting urobilin to bilirubin is one that is easily impaired and appears to suffer in disorders of the liver before its other functions are appreciably affected. Further, with a normal kidney a slight excess of urobilin in the blood leads to its excretion in the urine, where it may be readily detected. The test for its presence is by means of Ehrlich's aldehyde reagent.

This solution—whose full name is para-dimethyl-amino-benzaldehyde—is readily obtainable and keeps fairly well in a dark coloured bottle. About 20 drops are added to an inch or so of urine in a test-tube and the presence of urobilin is shown by the appearance of a bright red colour which is apparent immediately in the cold if large amounts are present, more slowly reaching its maximum in one to three minutes if the amounts are only moderate, and producing only a faint tint on warming if there are only traces.

A strongly positive result with this test is always pathological, but slight traces of urobilin may sometimes appear in the afternoon urine of healthy people. The significance of a positive result is twofold. Firstly, it occurs in conditions where an excess of blood is being broken down; and, secondly, in conditions where liver function is defective. It is thus a simple and valuable test for disorders of the liver and for those of blood destruction. As a rule it is readily possible to distinguish which factor is at work, though both may sometimes be combined. The commonest of the two is that of liver impairment, and the value of this test in two or three common types of liver disorder is undoubted.

Urobilinuria and Defective Function of the Liver.

In *cirrhosis of the liver* the test is usually strongly positive and with other evidence is of very real diagnostic assistance; it may be positive before other tests of hepatic function—such as the lævulose and galactose tolerance tests—show signs of insufficiency. Urobilin has also been shown by many workers to be constantly present in the urine after acute alcoholic excess, and this has even been urged as a legal point in those difficult cases of "drunk-in-charge-of-a-car." Its presence is at least evidence of the temporary damage to the liver which may be produced by alcoholic intoxication.

---

[1] THE LANCET, 1928, i., 741.

Secondly, in *catarrhal jaundice*, which we now know to be mainly toxic and not obstructive in nature, the test is positive at a very early stage, considerably before the appearance of the true bile-pigments which give the tests with iodine or nitric acid.

Thirdly, in *heart failure*, the test may be helpful, for an early sign of decompensation is the appearance of urobilin in the urine due to slight congestion of the liver; this, as is well known, may often occur before obvious signs such as dyspnœa, cyanosis, and gross œdema supervene. The dyspepsia and mild abdominal discomfort of apparently compensated mitral cases are often due to slight hepatic engorgement, and in such patients considerable amounts of urobilin may be present in the urine.

There is, moreover, a further point in this connexion to which I should like to call attention. As I stated, a normal kidney will excrete urobilin when it is present in the blood in only very slight excess. In nephritis this power is lost. Urobilinuria is thus an important consideration in cases of frank heart failure due to renal disease; in, for example, the common type of patient of, say, 50 to 60, who is brought to hospital with sudden acute heart failure, severe dyspnœa, œdema, cyanosis, and often auricular fibrillation. The vessels may be thickened, but the blood pressure may have fallen very low; there is often advanced emphysema and bronchitis, and it is sometimes difficult to know if the condition is primarily one of high blood pressure with "renal heart failure," or is the result of chronic pulmonary disease, myocardial degeneration, or pre-existing valvular lesions. The condition of the urine may be almost diagnostic. The usual features of heart failure urine are, briefly, small volume, high specific gravity, great acidity, with generally the presence of a large excess of uric acid. In renal heart failure the specific gravity is not so high—always an extremely bad sign in decompensated hearts—and Ehrlich's aldehyde test is negative; in heart failure with congestion of the kidneys but no previous renal disease there is abundant urobilin in the urine and a red colour appears immediately with Ehrlich's reagent. Thus in heart failure a urine of low specific gravity which gives a negative reaction for urobilin is of very grave significance, and suggests great care in the administration of diuretics, particularly of the new mercurial types, such as novarsurol or salyrgan, or even the simpler drugs such as calomel itself.

Whilst speaking of the subject of the urine in heart failure, I may perhaps mention a test which has recently been introduced from America and has been highly spoken of in Vienna and elsewhere, though I cannot myself vouch for its accuracy. It may be put in the form of an aphorism and is simply this: "*If the urine in heart failure remains acid to methyl-red in spite of treatment, the patient will not recover.*" A few drops of this indicator, which is readily to be had, are added to about 5 c.cm. of urine, and high acidity is shown by a permanent red colour, using a control of the untreated urine; when the acidity lessens the indicator gives only a yellow colour. Thus if the urine remains red to methyl-red in spite of treatment, the prognosis must be considered hopeless. I would commend this test as possibly useful, but it requires confirmation in a larger number of cases.

Urobilinuria in Hæmolytic Conditions.

Returning to the second uses of the test for urobilin in the urine, its value is more limited. It is positive in conditions of excessive hæmolysis or blood destruction, such as occurs in malaria, the most important of which is pernicious anæmia. Here, owing to the abnormal hæmolysis, a positive aldehyde reaction is almost constant, and this fact may be useful in the differential diagnosis of pernicious anæmia from, for instance, carcinoma of the stomach. There is often a lemon-yellow tint of the skin in both diseases; in both there are abdominal symptoms, and radiography and blood examinations are not always easily obtainable. In a case with these symptoms a positive urobilin test is highly suggestive of a hæmolytic anæmia, and demands a full blood count without delay.

In all forms of hæmolytic jaundice—of which pernicious anæmia is an example—large amounts of urobilin are present in the urine unless there is associated severe nephritis. In obstructive jaundice it is necessarily absent, since no bile can reach the intestine to be converted into urobilin. The test may thus distinguish between hæmolytic jaundice, in which it is positive but the iodine test is negative, and obstructive jaundice, in which it is negative but iodine shows the presence of unaltered bilirubin. In such conditions the van den Bergh reaction in the plasma may not always be decisive, and, moreover, possesses the great disadvantage that if the blood is not tested within at the most two to three hours after its withdrawal from the vein, the results are fallacious. It is thus futile to carry out this test on blood specimens delivered through the post.

Urobilin in Hæmorrhage.

In extensive internal hæmorrhage an excess of blood-pigment is absorbed into the blood, and large amounts of urobilin may be passed in the urine. The test is, therefore, used widely abroad in the differential diagnosis of such conditions as ruptured ectopic pregnancy, and has a particular value in the diagnosis of hæmorrhagic infarction. For example, in pulmonary infarction, which may often cause difficulty in diagnosis, the test becomes positive some six to eight hours after the infarction, and remains strongly positive during the first two or three days, while the bulk of the broken-down blood is being absorbed. The value of the test in this connexion is stressed by continental authorities, and I have myself watched the appearance and disappearance of urobilin in the urine in two such cases.

To sum up, Ehrlich's aldehyde reagent is a useful addition to the small list of urinary test substances which are required in practice, and with due appreciation of the causes that may lead to its appearance, the presence of urobilin in the urine is a valuable diagnostic sign. The reagent is also helpful, as I have mentioned, as giving a rough test for the detection of a raised urea-concentration in the blood, with which it gives a greeny-yellow colour to the otherwise colourless blood filtrate.

Biliary Drainage.

The next diagnostic aid of recent introduction that I want to describe is one which may perhaps be considered somewhat impracticable. It is the examination of the bile obtained by duodenal catheterisation. Although this procedure has not been widely taken up in this country, I feel that it has a considerable value. I have had the opportunity of carrying out such an examination in 51 cases so far, and would like briefly to mention a few points about its usage which I have mainly learnt from my own experience. The test demands a lot of patience—both from the physician and from the patient—but very little apparatus. For those who can afford the time necessary it is simple to carry out.

Technique of Duodenal Catheterisation.—An ordinary Einhorn fractional test-meal tube is used, which is about the diameter of No. 6 rubber catheter. This is swallowed by the patient (who should have fasted for at least eight hours) up to the first ring on the tube. There is rarely much difficulty in this and cocainisation of the throat is not advisable since sensation returns during the course of the test and may lead to serious retching at an inopportune moment.

The gastric contents are withdrawn and the stomach is washed out with a few syringefuls of distilled water. The tube is then pushed down to the second ring, a distance of 28 inches, and the patient is turned on to the right side with the buttocks raised by a pillow; this position aids the passage of the tube through the pyloric sphincter. This may take place almost at once, and is shown by the aspiration of a small quantity of alkaline bile-stained fluid—the duodenal content. It may, on the other hand, take a long time—often up to two or three hours—and one American investigator has recorded waiting 14 days for the tube to pass the pylorus! If there is delay I have found the sipping of a few ounces of very hot water useful, and slight withdrawal and reinsertion of the tube may sometimes be necessary; twice I have used atropine gr. 1/150 subcutaneously with success to aid relaxation of the sphincter. In general, however, the tube will pass in about one-half to two hours—the average time taken in my cases being one and three-quarter hours.

When the end of the tube is thought to be in the duodenum, a syringeful of water is blown in and if the tube is correctly placed this is not usually withdrawable; if it is still in the stomach the fluid can be at once sucked back, generally with a quantity of mucus. Fifty c.cm. of a 30 per cent. solution of magnesium sulphate are then slowly injected down the tube and some air is forced down after it. I inject the solution at ordinary room temperature, since I have found that warming it is apt to lead to nausea and regurgitation of the tube out of the duodenum; the magnesium sulphate is not as a rule withdrawable. After this, aspiration is carried out at short intervals, and normally the first bile-flow occurs within one to ten minutes. This flow is due to a reflex action from the duodenal mucous membrane and with healthy liver and biliary passages presents the following features. It is almost immediate in onset, rapid, painless, and of about 80 to 120 c.cm. volume. It shows, moreover, a typical gradation. First is a light yellow fluid, then a thick, dark green or brown viscid fluid, and finally it is of a clear golden limpid honey colour. The variations in these three types of bile—which are sometimes called A, B, and C bile—are important. The total flow usually lasts some 15 to 30 minutes.

Deductions from the Test.

I will not enter into the controversial subject of the exact origin of the three types of bile, and will merely refer briefly to some of the points in their examination by which this test may be of assistance. As with the urine and renal function, so may the rate and mode of secretion of the bile give almost as much information as a detailed chemical analysis of its constituents.

Complete failure to obtain bile on two repeated occasions is strong evidence of a stone in the bile passages. In association with jaundice it is almost conclusive of mechanical obstruction. It may thus be helpful in the diagnosis, for example, of carcinoma of the head of the pancreas from severe catarrhal jaundice, which is not always accurately possible by clinical means, and blood, urine, and stool examinations alone. Failure to obtain concentrated bile (bile B) can, though I think rarely, occur with healthy liver and biliary passages, but it is very unusual in the absence of disease to fail to obtain any bile at all if the test is carefully carried out. At the same time in a certain number of cases the attempt may have to be abandoned without it being certain that no bile could be obtained, on account of technical failure generally due to a revolt on the part of patient! In eight of the cases I have examined I must admit to complete non-success on these grounds. Pain during the flow suggests stone and infection in the gall-bladder. A very slow secretion with delayed onset and scanty volume seems also to be found—and I have observed this myself—in cholecystitis with or without stone.

In laboratory examination of the bile, as of the urine, the microscopic findings are of great importance. The presence of pus cells in the concentrated bile, often with many epithelial cells, is typical of cholecystitis; cholesterol crystals are not commonly seen, and when present in fair number are very suggestive of stone. Calcium bilirubinate crystals, which are very fine needles often clumped together into irregular masses, do not have such definite significance, and are often present in apparently normal patients. A large amount of albumin is present with biliary infection, but may also occur with disorder of the liver apart from infection. The normal in my cases has been less than ½ part per 1000, and more than 1 part per 1000 is always pathological. The presence of urobilin is also abnormal, and is seen especially with impaired hepatic function. In my cases large amounts have been present in ten and traces in four.

Catheterisation and Cholecystography.

I have not attempted to go into any detail about this test because I do not feel that its results are at present definite enough to warrant its use as an absolutely general procedure. It requires some practice both in performance and in the interpretation of results. Undue claims have, I think, been made for biliary drainage, just as undue claims were made when the fractional test-meal was first introduced. It nevertheless offers a very real aid in the diagnosis of cholecystitis and cholelithiasis and should, I think, be always employed where the existence of these conditions is in doubt. Its results should be viewed in association with those of radiography of the gall-bladder—a means of diagnosis which is also open to certain fallacies. With the use of the dye methods introduced by Graham a great advance has been made, but the method is still far from perfect, and I should like to say a few words about why this is so.

The dye most commonly used is sodium tetra-iodo-phenolphthalein, and is generally given by mouth; at St. Mary's Hospital we are using a preparation named shadowcol, distributed by Messrs. Kodak, which causes very little nausea or diarrhœa. After absorption from the intestine the dye is excreted by the liver into the bile, and reaches the gall-bladder by way of the cystic duct. In the gall-bladder water is absorbed and the dye becomes concentrated so that it is sufficiently opaque to give a shadow on a radiographic film. The densest shadow is thus seen when the patient is a normal subject, and there may be no shadow for one or more of the following reasons: (1) The dye is not sufficiently absorbed from the alimentary tract. (2) The liver is unable to excrete it efficiently. (3) The cystic duct is blocked and bile cannot reach the gall-bladder; or (4) the gall-bladder is incapable of concentrating its contents satisfactorily.

With so many factors involved it is clear why cholecystographic results are not correct in probably more than 50 to 60 per cent. of cases examined. In association with results of biliary drainage, however, they gain in importance, and I feel that a direct examination of the bile is likely to increase in value in the near future. As to its application to bacteriological investigations there is as yet hardly sufficient evidence to speak at all definitely, but it seems to be of real help in the investigation of latent focal sepsis in the gall-bladder. To sum up, I would say that it should always be used when possible in doubtful cases of gall-bladder disease, and would stress especially the importance in diagnosis of pain during the flow, of the rapidity, volume, and appearance of the bile, and of the presence of pus, epithelial cells, and cholesterol crystals in the centrifuged deposit.

INDIGESTION.

In conclusion I should like to say a few words about the differential diagnosis of some of the causes of indigestion, with particular regard to the so-called functional dyspepsias. The common type of patient, most usually a woman, who has abdominal symptoms suggestive of perhaps a gastric ulcer, but in whom we feel confident that a "neurosis" is the true cause, may present great difficulty in diagnosis. Often enough the general behaviour of the patient is characteristic and the pain is usually one that gets worse on going to bed, but never wakes her up once she has got to sleep; it is probably fairly true that "a neurosis never woke a patient." At the same time we often wish for physical signs or laboratory tests that can confirm our suspicions and exclude organic disease.

Of the physical signs of neurosis there is no one alone that can be of genuine assistance, and even a combination of many together can only increase the probability of a functional condition. Of these signs I may mention the exaggerated deep reflexes, brisk abdominals, absent palate reflex, and the evidences of various stigmata of degeneration such as asymmetries and minor deformities. To these is often added a condition of excessive vasomotor irritability or dermographia, in which a wide red mark rapidly appears after quite gently stroking the skin with a blunt instrument. There is frequently a tachycardia and a low blood pressure which reacts abnormally to mild exertion. A further sign which is not commonly present in persons of "non-neurotic nature" is an absence of the corneal reflex, which is perhaps the most suggestive of all the multitudinous signs of "neurasthenia" that have been proposed.

All these signs, however, are notoriously unreliable and laboratory aids in investigating the case are of real importance. Of these I would especially mention the value of an examination of the stools for *occult blood*, the finding of which definitely excludes a functional condition. It is so readily detectable that it should be looked for in all cases in which the possibility of ulcer or growth arises. In peptic ulcer intermittent bleeding is very common, and in carcinoma of the stomach occult blood is seldom absent and often continuous.

The test is very easily carried out, and the patient need only exclude meat (and meat extractives such as soup), fish, and green vegetables for two days from his diet. The simplest and most reliable technique is that of Gregerson, with the aid of benzidin tablets (benzidin 0·025 g. and barium peroxide 0·2 g.) obtainable from any chemist. One tablet or powder is dissolved in 5 to 10 c.cm. of strong acetic acid (50 per cent.), and a small particle of stool is rubbed up on the end of a match with a few drops of this solution. A positive result is shown by a green to deep blue colour appearing at once or within one to two minutes.

The use of these powders not only simplifies the test considerably, but excludes some of the fallacies of other methods of detecting occult blood. Indeed, A. G. Ogilvie considers that a blue colour obtained within 30 seconds is proof of occult blood in the stools entirely irrespective of the patient's previous diet. I realise that the test is well known, but I think it deserves more frequent application in general practice.

Test-meal analyses are, I am afraid, seldom of great assistance except in carcinoma of the stomach, pernicious anæmia, and duodenal ulcer. In the reflex and toxic dyspepsias of pulmonary tuberculosis, gall-bladder disease, renal disease, or chronic appendicitis, for example, the variations in gastric secretions are so diversely reported that assessment of their true significance is extremely difficult. In functional dyspepsia all types of test-meal results may be obtained.

There is one further test, which is old in origin but recent in its general utilisation, which may be employed with advantage in such cases—namely, the *red cell sedimentation test*. In spite of all that has been written and claimed for this test, especially in relation to pulmonary tuberculosis, the evidence of recent years shows that its real and great practical value lies simply in the differentiation of organic disease from functional disorder. It is in no way specific for any one form of disease, although exaggerated claims have often been made in this respect. It is a test that determines merely the rate at which the red cells fall to the bottom in citrated blood, and even now, in spite of the immense amount of work that has been done upon it, we do not know the exact factors that control this rate of sedimentation. Four volumes of blood are mixed with one volume of 3·8 per cent. sodium citrate and the rate of sinking of the red cells in this dilution is normally slow. I will not describe the exact details of the test, the results of which are recorded either in terms of the time taken for the cells to reach a given height in a standard tube (Westergren-Fahraeus) or of the height reached at a given interval of time (Linzenmeier).

In organic disease, especially where any form of tissue destruction is occurring, the rate of sedimentation is considerably increased. It has now been completely demonstrated that in a given case rapid sinking of the red cells above the normal rate excludes the diagnosis of a purely functional disorder.* A normal rate is unfortunately by no means such certain evidence of the *absence* of organic disease. In suspected gastric neurosis or other functional disorders, therefore, a normal sedimentation rate is confirmatory only of the diagnosis, whilst on the other hand a rapid sedimentation must make us immediately turn to an organic cause for the symptoms concerned. In this somewhat limited field of usefulness this simple and inexpensive test has, I think, a definite value. The details may be found in any recent text-book.

SYPHILIS OF THE LUNG WITH PULMONARY ARTERITIS (AYERZA'S DISEASE).

BY GEOFFREY L. S. KONSTAM, M.D. LOND., M.R.C.P. LOND.,
MEDICAL FIRST ASSISTANT AND REGISTRAR, LONDON HOSPITAL.
(From the Cardiographic Department, London Hospital.)

With a Report upon the Pathological Findings by
Prof. HUBERT M. TURNBULL, D.M. Oxf.,
DIRECTOR OF THE BERNHARD BARON INSTITUTE OF PATHOLOGY, LONDON HOSPITAL.

MORE than a hundred years ago Laënnec described dilatation of the pulmonary artery in chronic affections of the lungs.[1] Andral, in 1829,[2] stated that most of the lesions which occur in the aorta are also to be found in the pulmonary artery, but much more rarely. Huchard, in 1893,[3] drew up a table of arteries showing their liability to atheroma. He quoted similar tables by Rokitansky and Lobstein confirming his conclusion that the pulmonary artery is, of all the large arteries in the body, one of the least liable to atheroma. Romberg, in 1891,[4] recorded a case of a man aged 24, in which there was extensive sclerosis throughout the pulmonary artery and its branches and hypertrophy of the right ventricle without apparent cause. Dyspnœa and cyanosis of the skin and mucous membranes were prominent symptoms for many months before death.

Sansom, in 1896,[5] working at the London Hospital, summarised the subject. He concluded that acute and subacute pulmonic endarteritis are mostly due to the extension of septic endocarditis, but that the inflammation may be due to syphilis. In discussing chronic, endarteritis and atheroma of the pulmonary artery he mentioned congenital defects, mitral stenosis, and obstructive diseases of the lung as important ætiological factors.

In 1901, Abel Ayerza, professor of medicine in the National University of Buenos Aires, drew attention in an unpublished clinical lecture to the morbid entity of "cardiacos negros," a syndrome which Escudero[6] claims to have shown in 1905 to be associated with generalised sclerosis of the pulmonary artery and hypertrophy of the right ventricle. Though these two workers had so far only confirmed Romberg's observations we find the term Ayerza's disease, which was used for the first time by Marty in 1909,[7] creeping into general use. Leonard Rogers, in 1909,[8] writing on nine Bengalis suffering from primary atheroma of the pulmonary artery accompanied by extreme right heart hypertrophy but without valvular lesions, concluded that the extensive atheroma of the whole of the pulmonary arteries was syphilitic in origin. The symptoms from which his patients suffered were palpitations, dyspnœa, and dropsy; he did not stress cyanosis. Escudero, however, in 1911,[6] revised his opinion of the pathological basis of "cardiacos negros" in that he now associated the sclerosis of the pulmonary artery with bronchial syphilis.

Advances in the diagnosis of lesions of the pulmonary artery were made by Posselt in 1908[9] who emphasised the importance of radiological and electrocardiographic findings.

---

* A rapid sedimentation is normal during the early months of pregnancy.

Arrillaga,[10] in 1913, in a monograph, the English translation of which was kindly lent to me by Dr. Geoffrey Evans, gave a detailed account of "cardiacos negros." His main conclusions were as follows:—

1. The ætiological factors of "cardiacos negros" are chronic pulmonary disease processes, asthma, chronic bronchitis, tuberculosis, and pleural adhesions—in short, all disturbances which have as their final result a state of pulmonary emphysema.

2. These processes evoke, in a pulmonary artery, rendered sensitive by slow infections such as syphilis, paludism, &c., or by intoxications, a sclerotic process which causes a physiological stenosis of the arterial tract which the blood *follows on its way to oxygenation.*

3. This sclerosis of the pulmonary artery can not only be demonstrated microscopically and histologically in the specimens obtained from these patients, but may also be recognised clinically in hæmoptysis, cyanosis, dyspnœa, and hypercyanotic angina, from which these patients suffer.

4. The right heart undergoes an enormous hypertrophy involving both the auricle and the ventricle which are forced to struggle against the obstacle in the peripheral circulation.

5. This hypertrophy, as well as the dilatation of the pulmonary artery in its early stages, can be clearly seen by radioscopy and radiophotography.

6. The principal symptoms of this entity are: cyanosis, polycythæmia, dyspnœa, cough with mucous or mucopurulent expectoration, cephalalgia, hypercyanotic angina, hæmoptysis, vertigo, an overpowering desire for sleep, &c.

7. *The pulmonary stage is a very long one; after about* 20 years as a pulmonary complaint it comes to the notice of the clinician in its cardiac phase.

8. The course of the "cardiacos negros" stage is also long and varies from two to five years.

9. Some of the patients may end as "cardiacos negros" and after showing the right gallop rhythm die in their sleep, without having suffered from a trace of œdema. Others, in whom degeneration of the cardiac fibre had taken place, early succumb to ordinary asystole caused by failure of the right heart and die in a state of advanced anasarca. Finally, some die of complications, of which the commonest is broncho-pneumonia.

In subsequent writings, Arrillaga [11] [12] insists more positively that syphilis is the essential ætiological factor in the evolution of the "cardiacos negros" and that chronic cardiopulmonary diseases play only a subsidiary part.

Of recent years there have been many contributions, American and European, to the literature of sclerosis of the pulmonary artery. Warthin, in 1917,[13] demonstrated for the first time the *Spironema pallidum* in the wall of the pulmonary artery in a case of syphilitic arteritis and aneurysm of this vessel. Four years later Elizaldo confirmed this finding in one of Arrillaga's patients[14] who had a history of syphilis and a positive Wassermann reaction. M. Giroux, in 1910,[15] and Marcel Thomas, in 1927,[16] contributed detailed theses on lesions of the pulmonary artery. Cheney,[17] in the same year, reported two cases of Ayerza's disease, and concluded that the term should be restricted to cases of sclerosis of the pulmonary artery and hypertrophy of the right heart due to syphilis. Clarke, Coombs, Hadfield, and Todd [21] recently published details of five cases of congenital and acquired lesions of the pulmonary artery which had come to autopsy.

"Primary" Sclerosis of the Pulmonary Artery.

Though many authors have published cases of so-called primary sclerosis (non-syphilitic) of the pulmonary artery the existence of such an entity is in doubt.

Prof. H. M. Turnbull in his early[18] and later work upon the arteries has found thickening of the pulmonary arteries to be almost entirely intimal. The intimal thickenings are composed either of layers of muscle and elastic fibres, which have usually undergone a greater or less degeneration, or of granulation tissue, the endarteritis fibrosa of Jores.

In the formation of the layers of muscle and elastic fibres the elastic stripe separates from the elastic lamella and proliferates. Layers of muscle and elastic fibres of similar structure are normally developed in a similar manner during early years in the aorta and its large elastic branches. An increase in magnitude of the intimal layers of muscle and elastic fibres in these arteries and their development in other arteries can only be regarded as a hypertrophy. Hypertrophied intima is prone to degeneration, particularly in older subjects. Slight intimal hypertrophy is found in the pulmonary arteries of the elderly, and is doubtless due to medial degeneration; one or two minute flecks of atheroma can usually be detected on careful examination with the naked eye, and more extensive focal degeneration of the intima is found under the microscope. Greater degrees of intimal hypertrophy, with greater degeneration, are found in mitral stenosis and all other *conditions causing an obstruction to the circulation* in the lungs.

Far the commonest form of intimal degeneration in the pulmonary arteries is a degeneration that is superimposed upon hypertrophy and is independent of inflammation. From his experience of the aorta, however, Prof. Turnbull has no doubt that intimal degeneration may complicate chronic inflammation of the pulmonary stem and large branches, although he has not personally had an example. When syphilitic aortitis is confined to the adventitia and media, the overlying intima may hypertrophy and then undergo atheromatous degeneration. Usually the aortitis implicates the intima and causes a granulo*matous thickening. When this inflammatory thickening* has become sclerotic it usually becomes impregnated with calcium or undergoes true fatty and calcareous atheroma, just as calcareous impregnation and atheroma tend to affect cardiac valves which have been sclerosed by chronic inflammation. Such degenerations secondary to inflammation may doubtless, therefore, occur on the rare occasions when the pulmonary stem and large branches are affected by syphilitic inflammation. In syphilitic and tuberculous arteritis of the smaller pulmonary arteries, and the small arteries in other organs, he has not seen secondary degeneration.

Such intimal degeneration of the larger pulmonary arteries, although a secondary complication of syphilitic inflammation of these larger arteries, might be called primary, in so far as it is not secondary to obstruction within the lungs. Prof. Turnbull has not had an example of such degeneration of the intima of the pulmonary arteries superimposed upon syphilitic or tuberculous inflammation of the subjacent coats. His cases belong to the group in which there is no underlying inflammation. When, in his experience, there has been degenerative thickening of the intima of the pulmonary arteries, there has always been histological evidence of intimal hypertrophy having preceded the degeneration; when the hypertrophy and degeneration have been great, there has always been an obvious cause of obstruction to the pulmonary circulation. He has therefore found no evidence of a primary, non-inflammatory sclerosis of the pulmonary arteries, except the slight atherosclerosis of elderly subjects.

Definition of Ayerza's Disease.

There can be little doubt that many of the cases referred to by Arrillaga in his thesis[10] on "cardiacos negros" belonged to the already well-known group of chronic cardiopulmonary diseases producing right heart hypertrophy and later failure. Parkinson and Clark-Kennedy's paper on Heart Failure with Normal Rhythm[19] includes a series of such cases. Intimal hypertrophy and degeneration of the pulmonary arteries in such cases were also well known as secondary effects.

The clinical manifestations of such a sequence of events are cyanosis, dyspnœa, hæmoptysis, clubbing of the fingers, and secondary erythrocythæmia. The signs and symptoms of congestive heart failure are usually superadded before death.

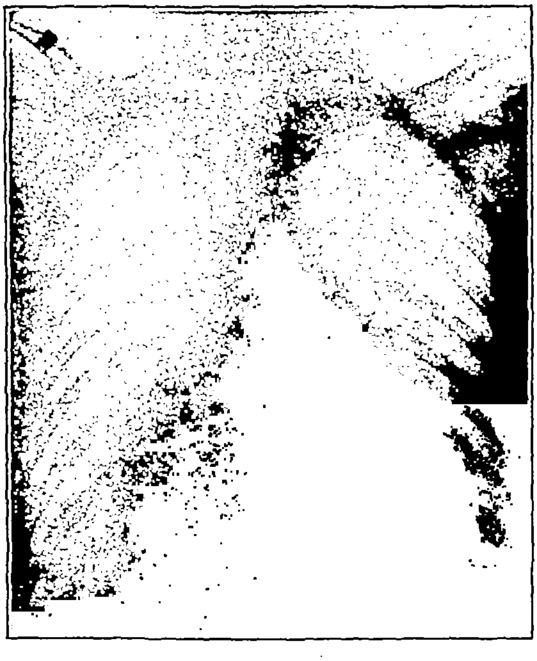
Ayerza has left no written account of his observations, but if we are to accept his pupil Arrillaga's writings as embodying the teaching of his master, Ayerza's claim to a place in medical nosology must be based on his discovery of the "black cardiac" syndrome due to *syphilis* of the lung and pulmonary arteries. The many accurate macroscopic and microscopic descriptions of undoubted syphilitic pulmonary arteritis, confirmed by Warthin and Elizaldo's demonstration of the *Spironema pallidum* in the wall of such arteries, have placed the existence of this entity on a sound footing. Now just as emphysema and non-specific fibrosis of the lungs may, by causing obstruction and hypertension in the lesser circulation, induce intimal hypertrophy and degeneration of the pulmonary artery so also can peribronchial and interstitial pulmonary syphilis induce these changes.

In the case here reported the smaller branches are the seat of obliterating syphilitic arteritis, whereas the pulmonary stem and main branches show the changes due to hypertension—namely, intimal hypertrophy with superimposed atheromatous degeneration.

Clinical Features.

Both sexes are affected about equally, there being 15 men out of 27 cases collected from the literature by Cheney. He says that cases have been recorded in Europe, South America, United States, and India. The patient usually *does not present himself with* typical symptoms until he has reached the age-period 20–50 years. Cough and expectoration may have been present for many years. Gradually dyspnœa, cyanosis, persistent headache, and drowsiness become added to the picture. Orthopnœa is the rule, and hæmoptysis is common. Oppression in the chest, particularly after exertion, may be a prominent symptom. The somnolence often considerably mitigates the patient's sufferings and may be partly responsible for prolonging the life of the patient after extreme cyanosis has developed. Congestive heart failure more frequently than not supervenes before death. The cardiaco negro may die, however, in his sleep without manifesting any of the signs or symptoms of heart failure.

FIG. 1.



Antero-posterior radiogram of chest. The enlarged globular shadow of the heart is seen. On its left border the prominence immediately below the small aortic knuckle is the pulmonary artery which is larger and denser than normal; the mottling in the lower lung-fields is due to fibrosis and congestion.

Though the average case runs a protracted course over many years, others such as ours die within two years of their first symptom.

On examination the temperature is often subnormal; the pulse and respiration-rate may be 100 and 30 respectively. Cyanosis of the head and neck, mucous membranes, conjunctivæ, and periphery of the limbs is a striking feature even *when the* patient is at rest; that of the buccal mucosa often extends to the soft palate and posterior pharyngeal wall. The pulse is regular, and the palpable arteries are not unusually thickened. Clubbing of the fingers is usually seen. The blood pressure is within normal limits. Cardiac and hepatic dullness may be encroached upon by lung resonance; the heart sounds will then be distant. Unless emphysema is too great systolic pulsation in the pulmonary artery can be seen and palpated, and the pulmonary *second* sound is accentuated.

Five to fifteen ounces of muco-purulent sputum may be expectorated daily. The accessory muscles of respiration, particularly the scalenes, hold the barrel-shaped chest in the position of full inspiration. Lung resonance is increased and on auscultation loss of vesicular murmur and prolonged expiration is heard. Rhonchi and crepitations are heard at the bases.

General anasarca and hepatic enlargement depend on whether congestive heart failure has occurred or not. Blood examination shows a red count of between five and ten million, the hæmoglobin being above normal and the colour-index below 1.

Radiological Examination.

1. The heart shadow is much enlarged both to the right and to the left, giving a globular appearance. 2. The enlarged pulmonary artery is seen vigorously pulsating below the aortic knuckle, which seems small by comparison. A half turn of the patient to the left (first oblique position) gives an even better idea of the size of the pulmonary artery, which may even reach aneurysmal proportions.[20] Each pulsation will be seen to follow immediately upon ventricular systole. 3. The shadows of both lung roots are abnormally large and dense and the component arteries may visibly pulsate; shadows radiating from them into the lung parenchyma may be due to vascular engorgement or to fibrosis. 4. Evidences of emphysema may be found, such as horizontal position of the clavicles and ribs, wide intercostal spaces, and low position of the diaphragm with diminished movement. An electrocardiogram will show striking right ventricular predominance.

Differential Diagnosis.

Any disease process leading to pulmonary hypertension may produce symptoms clinically indistinguishable from Ayerza's disease. Chronic disease of the lung and pleura, chronic valvular lesions of the heart, particularly mitral stenosis, congenital morbus cordis, malformations of the pulmonary artery, thoracic deformities should all be excluded before the diagnosis is suggested.

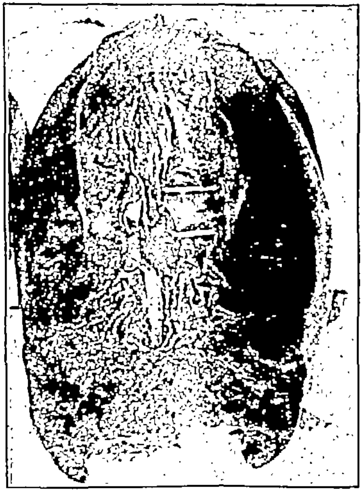
Difficulty may arise in differentiating other causes of cyanosis, especially erythræmia (Vaquez-Osler *disease*). Reliance must be placed on the clinical, radiographic, and electrocardiographic evidence of dilatation and hypertrophy of the right ventricle and pulmonary artery together with evidence of syphilis in those exhibiting Ayerza's syndrome. The spleen is not usually palpable and the blood pressure is normal. Blood counts may be identical in the two conditions.

Enlarged mediastinal glands, thoracic tumours, and aortic aneurysms may, by obstructing the superior vena cava, cause congestion and cyanosis of the head and neck. The limited distribution of the cyanosis, the enlargement of the superficial collateral circulation, and radiographic examination make the diagnosis easy. Mediastinal tumours and aneurysms, however, by pressing on the pulmonary artery may cause difficulty. Congenital morbus cordis, even when unassociated with marked abnormality of the pulmonary artery, may be the cause of extreme cyanosis. It should also be borne in mind that aneurysm of the pulmonary artery may occur as a congenital *abnormality*; Bedford [20] reports an example of this complicated by infective endocarditis.

Treatment.

Prophylaxis and treatment whilst the disease is in its pulmonary stage offer the best chances of success. Once cyanosis has become established little can be done apart from symptomatic treatment. Even if the Wassermann reaction is negative antisyphilitic remedies should be given if there is a positive history or if there are signs of old visceral or cutaneous lesions. In the presence of persistent headache or frequently recurring hæmoptyses venesection should be employed. Oxygen administered by the intranasal method and other measures usual in cardiac failure from other causes may help.

FIG. 2.



Section through the left lung. The larger pulmonary arteries are greatly dilated and have thickened walls. The lower lobe is seen to extend almost as far as the apex of the lung and largely replaces the shrunken fibrotic upper lobe, which has retracted inwards. Inferiorly many dilated and thick-walled bronchioles lie closely packed together; around these a reticular fibrosis is clearly shown.

Illustrative Case.

A.B., a male nurse, aged 45, was admitted to the London Hospital with a history of 18 months' increasing dyspnœa which was worse on exertion. Five months previously he had had two small hæmoptyses, the sputum being only tinged with blood. A month later he noticed that his lips were blue and that his feet became swollen after exercise. Cough was never a prominent symptom.

Past History.—31 years before he had had typhoid fever, and 25 years before he had had ulcers on the soft palate, which left two small perforations.

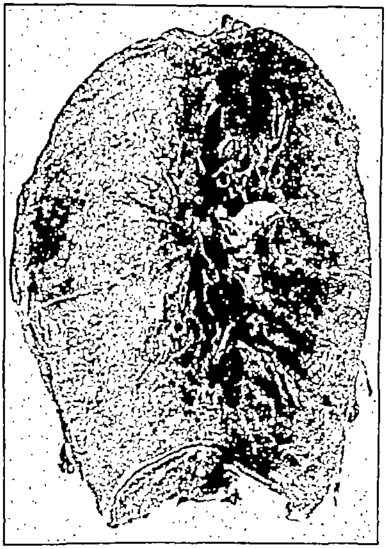
On Examination.—Cyanosis of lips, ears, cheeks, and feet. Orthopnœa present. Considerable œdema of the feet, legs, thighs, and lumbar region. Extensive tattoo marks over trunk and limbs. Moderate clubbing of the fingers, and cyanosis of the nail-beds. Two small perforations of the soft palate slightly to the left of the mid-line and close to the junction of the hard and soft palate. Small white scar on under surface of glans penis.

Circulatory System.—Pulse 100, regular, and of moderate volume. Blood pressure 120–180. Brachial and radial arteries not thickened. Apex-beat not defined, left border of cardiac dullness one inch external to the left nipple line. Heart sounds normal.

Respiratory System.—Sputum, three ounces of mucopurulent sputum daily. Chest held in position of full inspiration. Scalene muscles in action during inspiration. Inspiration everywhere harsh and expiration prolonged. Coarse crepitations at both bases, more numerous on the left side.

Abdomen slightly distended, lower border of liver palpable two fingers-breadth below the costal margin. No tenderness over the liver. Spleen and kidneys not palpable.

FIG. 3.



Section through the right lung. The dilated and thickened larger pulmonary arteries are seen in longitudinal and transverse section. A delicate reticular fibrosis is conspicuous in the greater part of both the upper and lower lobes. In the base larger fibrous trabeculæ and stellate patches of fibrosis are present in addition.

Nervous System.—Pupils equal, react to light and accommodation. Knee-jerks and ankle-jerks equal and active. Bilateral flexor plantar response.

Reports.—Urine free from albumin and sugar. Wassermann reaction *positive* in serum. *Blood-urea*, 0·034 *per cent.* White cell count, 7120. Polymorphonuclear leucocytes, 65 per cent., large hyaline cells 11·5 per cent., small lymphocytes, 20 per cent., large lymphocytes 3·5 per cent. By an oversight the total number of red blood corpuscles and the hæmoglobin value were not estimated.

Radiographic Examination (Dr. George Vilvandré).—Enlargement of the heart to the right and left, the cardiac shadow presenting a globular appearance. Left border of the heart ¾ in. external to the mid-clavicular line. Pulmonary artery unduly prominent, lying below the normal aortic knuckle (Fig. 1). Both lung roots obscured by the large cardiac shadow. General coarse mottling shown by the bases of lungs.

Electrocardiogram.—Right ventricular predominance. A negative "T" in leads II. and III. due possibly to digitalis.

Course.—Digitalis was given without benefit until coupling took place, a polygram showing alternate ventricular premature beats. Despite the administration also of diuretin, iodides, and mercury the œdema increased, and the amount of urine decreased from 60 to 8 ounces per diem. The pulse continued regular except for the above-mentioned digitalis coupling, and varied between 56 and 110 until just before death when it rose to 120. The patient died four weeks after admission, the temperature remaining between 96 and 97° F. during the whole period.

This patient, admitted with cyanosis, severe though by no means black, with congestive heart failure, with œdema, yet with normal heart sounds, was at first regarded as a case of heart failure with normal rhythm, probably due to syphilis affecting the orifices of the coronary arteries (Wassermann reaction positive; perforated palate). The X ray appearance showing no aortic enlargement but prominence of the pulmonary artery shed doubt on the preliminary diagnosis and it was not until the necropsy that the exact nature of the underlying lesion was determined.

I am indebted to Dr. John Parkinson for his advice and for permission to publish the notes of this case, and to Dr. D. Evan Bedford for help with the bibliography, and to Prof. Hubert Turnbull for his remarks upon degeneration of the pulmonary arteries, and for his report upon the necropsy.

REPORT UPON PATHOLOGICAL FINDINGS.

BY HUBERT M. TURNBULL.

Summary of necropsy (P.M. 446. 1928).—Failure of hypertrophied right heart. Syphilitic interstitial fibrosis of lungs and extensive endarteritis of pulmonary arteries.

Anthracosis and plasma-cell infiltration of bronchial glands. Conspicuous patchy atheroma of hypertrophied intima of pulmonary stem and of branches not affected by arteritis. Lumen of pulmonary stem, 8·5 cm. in circumference; wall, 0·1 cm. thick; lumen of ascending aorta, 7·5 cm. in circumference. Slight atheroma of arteries of greater circulation. Great hypertrophy and dilatation of right ventricle and auricle; slight atrophy of left ventricle. Foramen ovale closed. Milk spots on anterior surface of right ventricle and posterior surface of right auricle. Congestion and confluent central back-pressure atrophy of liver. Back-pressure spleen and kidneys. Great congestion of stomach; area (2·2 by 1·5 cm.) of purulent streptococcal inflammation and necrosis of centre of posterior wall of body of stomach. Area (2·5 by 1·1 by 1·3 cm.) of purulent hæmorrhagic inflammation and fat necrosis in subjacent portion of body of pancreas. Great submucous œdema of cæcum and ascending colon; œdema of bone marrow; general anasarca, greatest in feet, legs, and back; ascites (907·2 c.cm.). A few patches of fatty hæmatogenous marrow in upper half of shaft of femur. Perforation (0·4 by 0·15 cm.), with healed and scarred margins, through anterior extremity of soft palate. Great fibrosis of faucial tonsils. Considerable syphilitic fibrosis of bodies of testicles, especially of left. Faint, slightly sunken, white scar on under surface of glans penis. Colloid adenoma (0·6 cm. diam.) in lower pole of left lobe of thyroid. Thymus masked by fat. A few scars (of war wounds) on right buttock. Healed amputation of second toe of right foot. Superficial erosion of skin over buttocks. Wasted man.

Weights: Body, 64·27 kg. (length 1·72 metre); brain, 1318·3 g.; liver, 1234·0 g.; heart, 453·6 g.; kidneys, 368·7 g.; spleen, 212·6 g.; pancreas, 98·7 g.; thyroid, 20 g.; thymus, 14·2 g.; suprarenal bodies, 11·3 g.; pituitary body, 0·6 g.

Macroscopic Appearances.

The thickened parietal and visceral pleuræ were everywhere either completely fused or bound together by a net of fibrous sheets and trabeculæ. In places they could be torn apart so as to expose a visceral layer which was milky-white and either quite opaque or sufficiently translucent to show a background of dark slate. Cut surfaces of the lungs, except in the upper half of the posterior part of the left lower lobe and in the apex of the right lower lobe, had to the naked eye a conspicuously spongy appearance. A net of pearly fibrous tissue enclosed spaces, of which the larger were obviously dilated bronchioles and the smaller dilated vesicles. The fibrous septa of this sponge varied considerably in thickness in different places. Even the most delicate were clearly visible to the naked eye. Those bounding bronchioles were stouter than those bounding adjacent vesicles. Comparison of different areas showed that in general the stouter the septa were the larger were the pores. The sponge was traversed and interrupted by pearly branching trabeculæ about one millimetre broad and by pearly stellate patches about one centimetre in diameter. Some of these trabeculæ and patches could be seen to surround bronchi and large bronchioles; any bronchus or bronchiole which happened to be cut transversely in the centre of a patch was seen to be conspicuously dilated. Even in the areas mentioned above as not being spongy to the naked eye a delicate reticular fibrosis and a spongy structure were seen with a hand lens. The fibrosis was especially great throughout the left upper lobe, which was so shrunken that the lower lobe formed the apex of the left lung. It was also very great in the anterior part of both the upper and middle lobes of the right lung; here it enclosed many bronchi, which were considerably dilated and packed close to one another. In general it was greatest in the anterior and lower portions of the lobes, and there was no appearance of radiation from the hilum. The more fibrotic areas were distinctly more anthracotic than the less, and the shrunken left upper lobe was deeply anthracotic. The areas which were not spongy to the naked eye were of a rusty tinge. Very few small branches of the pulmonary artery could be recognised; most of these were unusually thick but otherwise of normal appearance, a few could be identified as solid cords of pearly-grey fibrous tissue. The larger pulmonary branches projected, and had conspicuously thick walls. When slit open their intima showed numerous opaque yellowish-white flecks and small buttons of atheroma. In the distal portion of the pulmonary stem were a few faint yellow flecks.

The necropsy was performed by Dr. W. W. Woods.

*Microscopic Examination.**

The visceral and parietal *pleuræ* are both greatly thickened by a dense collagenous fibrous tissue, and are intermittently fused. *The upper part of the lower lobe of the left lung* shows no abnormalities except emphysema, and engorgement of the larger capillaries and venules. All the other portions *of the lung show a great thickening by dense fibrous tissue* of the septa and of the adventitia common to the bronchi or bronchioles and their pulmonary artery. The dense fibrosis extends from the broncho-pulmonary adventitia along the adjacent walls of the alveolar passages and infundibula. Near the bronchi or bronchioles the air cavities have been completely replaced by fibrous tissue or are represented by a few small widely separated cavities. Further out the fibrotic thickening of the walls of the alveolar passages and infundibula diminishes progressively, but it is completely absent in only a very few areas. Such areas appear as islands in the fibrotic tissue. The alveoli with fibrotic walls are lined with a continuous row of oval or cubical cells. Where the fibrosis is greatest and has led to reduction in the size of the alveoli many of the alveoli contain round, desquamated epithelial cells.

The fibrotic tissue in the pleuræ and lung consists of stout collagen fibres and contains few fibrocytes; it shows patchy infiltration with lymphocytes, plasma cells, and a few eosinophil leucocytes.

The bronchioles are dilated. In the anterior part of the upper lobe of the right lung and the lower posterior part of the upper lobe of the left lung they are greatly dilated and are filled with mucus, which contains a variable number of desquamated epithelial cells and an occasional neutrophil leucocyte. Except where the air cavities have been almost completely obliterated by the interstitial fibrosis the respiratory bronchioles, alveolar passages and alveoli are conspicuously dilated; this dilatation is greater in the fibrotic areas than in the islands in which fibrosis is absent.

The number of capillaries is obviously reduced in the fibrotic alveolar walls, and is reduced in proportion to the amount of fibrosis. All capillaries throughout the fibrotic portions of the lung are greatly engorged but the engorgement is most striking in the included islands of lung tissue which are free from fibrosis. Here the walls of the alveoli are greatly widened and are moniliform in outline owing to the great distension of their engorged capillaries. There is much hæmorrhage into alveoli, and there are many small and a few large hæmorrhages into the interstitial tissue. The muscular tissue of the fibrotic portions of the lung is greatly hypertrophied. There is slight anthracosis in the site of lymphatics. Nowhere is there any infiltration with neutrophil leucocytes or any acute bronchitis or pneumonia.

In the *right main bronchus* many of the columnar epithelial cells are distended by mucus, there is a patchy infiltration of the mucosa with lymphocytes, plasma cells, and an occasional neutrophil or eosinophil leucocyte, and the mucous glands are infiltrated with plasma cells and lymphocytes.

---

* Portions were taken from the posterior border of the lower lobe and from near the anterior border of the upper lobe of the right lung; from the lower part of the posterior border of the upper lobe, including the adjacent part of the lower lobe, and from near the anterior border of the upper lobe of the left lung; from the right main bronchus, including a lymphatic gland; from the pulmonary stem; the right pulmonary artery; the left testicle; the body of the stomach; and the pancreas. After fixation in 4 per cent. saline formaldehyde they were embedded in paraffin; sections were stained with Ehrlich's hæmatoxylin and eosine, Weigert's iron hæmatoxylin, and van Gieson's mixture, Weigert's fuchselin and neutral red and, in some cases, Gram's stain and neutral red. Other portions were put through the Levaditi process for the demonstration of spirochætes, with a piece of congenitally syphilitic liver as control.

Few parabronchial *intrapulmonary pulmonary arteries* happen to be included in the sections. One such artery is occluded by endarteritis fibrosa; the others show considerable musculo-elastic hypertrophy of their intima. Some of the primary branches of these arteries and numerous pulmonary arteries of medium and small size are occluded by endarteritis fibrosa. The occluded lumen in some cases is narrowed, the media being crenated. The occluding tissue is sometimes composed of a reticulum of delicate collagenous fibrils and a few large spindle fibrocytes. It is sometimes sparsely infiltrated with lymphocytes and plasma cells. Usually it consists of very stout collagenous fibres and very few fibrocytes. It usually then contains delicate elastic fibrils. It is almost always canalised, and the canalising vessels usually comprise veins and capillaries as well as an artery. Sometimes, as in the case of the artery accompanying a bronchus, a large artery occupies almost the whole of the lumen of the old artery, being separated from the old media by a narrow zone of fibrous tissue containing capillaries. The canalising veins and arteries have muscular walls. Elastic fibrils are usually present in their walls; the fibrils are delicate and vary in number, but in many arteries they are as abundant as in a typical pulmonary artery. Most of the pulmonary arteries that are free from endarteritis fibrosa, especially the larger, show musculo-elastic hypertrophy of the intima. Secondary degeneration can sometimes be recognised by replacement of some of the muscle fibres by foam cells.

The *bronchial and pleural arteries* are free from endarteritis but usually show intimal hypertrophy. The pleuræ contain many wide veins. If *pulmonary veins* in the septa and pleura have been destroyed by endophlebitis their destruction has been complete, because there is now no recognisable remnant of their walls.

The intima of the *right pulmonary artery* is hypertrophied over four-fifths of the circumference, and is in places twice as thick as the media. Secondary degeneration is indicated by replacement of muscle fibres by many groups of cells which appear to be distended with fat, but paraffin sections are alone available.

The intima of the *pulmonary stem* is hypertrophied throughout the section, and in thickness has a ratio to the media which varies from 1 : 6 to 1 : 1·34. The hypertrophy is formed almost exclusively by the longitudinal musculo-elastic layer of Thoma. Many muscle fibres are replaced by foam cells.

The right *hilar lymphatic gland* is extremely engorged and the sinuses are filled with blood. There are numerous plasma cells in the lymphadenoid tissue.

In the left *testicle* there are large confluent areas of fibrosis. In these areas the tubules are obliterated by a great hyaline thickening of the fibrous layer internal to the elastic membrane, and the obliterated tubules are widely separated by dense fibrous tissue. In the centres of some areas the elastic membrane has been partially or completely destroyed. There is a slight infiltration with lymphocytes, plasma cells, and eosinophil leucocytes, particularly in the periphery of the fibrous areas. The large arteries show intimal hypertrophy; the lumina of many of the smaller arteries and veins are partially occluded by endarteritis fibrosa.

The *body of the stomach* is greatly engorged. In one section there is no other abnormality except an infiltration of the mucosa with plasma cells, which is usually confined to a narrow zone at the surface. In the section including the hæmorrhagic area there is in the submucosa a large area of œdema, dense infiltration with neutrophil leucocytes, and hæmorrhage; the walls of many veins are infiltrated and necrosed. The hæmorrhage and infiltration extend into the circular layer of the muscularis. The mucosa over the area is necrosed and at one spot its deeper layers are packed with neutrophil leucocytes. In the necrosed mucosa there are masses of Gram-positive cocci and bacilli; in the submucosa there are numerous Gram-positive cocci, diplococci, and streptococci in short chains, but only a few bacilli; some of the cocci lie within veins.

The *pancreas* shows a purulent pancreatitis with lipolysis, proteolysis, and hæmorrhage. There is infiltration and necrosis of the walls of some veins. The adipose tissue beneath the peritoneum of the lesser sac is densely infiltrated with neutrophil leucocytes. The duct of Wirsung is surrounded by infiltration and contains concretions and a few neutrophil leucocytes. A few Gram-positive diplococci were found on careful search.

Levaditi preparations.—In the sections so far examined no spironemata have been found; spironemata pallida are abundant in the control sections of syphilitic liver.

Remarks.

The necropsy showed that the essential cause of death was failure of the hypertrophied right heart. That the heart failure had been present for some time was shown by the severe "back-pressure" atrophy of the liver. The purulent streptococcal inflammation of the stomach and pancreas was obviously a subsidiary terminal event. As regards the cause of this terminal infection, the condition of the spleen appears to exclude pyæmia; the most likely explanation is a focal infection of the mucosa of the greatly engorged stomach and an infection of the subjacent pancreas by direct spread; the juxtaposition of the inflammation in the stomach and pancreas brings strong evidence in favour of this view.

The hypertrophy of the right heart, the failure of the heart, and the cyanosis observed during life are adequately explained by the condition in the lungs. First, there was a great loss of alveolar surface. Many alveoli had been completely destroyed by the interstitial fibrosis. Where the fibrosis was less the alveoli were greatly distended. The distension of these alveoli and the bronchiectasis were doubtless due to retraction of the peribronchial and peribronchiolitic fibrotic tissue. Such alveoli as were not fibrotic were distended to a less degree, those which lay as small islands in the fibrotic portions of lung being more distended than those which were not in close relation to fibrosis (the section of the upper part of the lower lobe of the left lung); but the lung in the latter position showed typical vesicular emphysema. Secondly, there was a great loss of capillaries in the walls of the fibrotic alveoli. Finally, most of the pulmonary arteries of medium and small size, and some of the large, parabronchial, were occluded by canalised endarteritis obliterans. These changes could not fail to cause great obstruction to the lesser circulation. Direct evidence of the obstruction caused by the reduction of the capillary area was shown by the intense engorgement of the remaining capillaries and by the intra-alveolar and interstitial hæmorrhages.

The inflammation in the lung had been of long duration. This was shown by the stoutness of the collagen fibres and the paucity of fibrocytes in the fibrotic pleura and pulmonary interstitial tissue, by the presence of elastic fibrils in the inflammatory tissue occluding the arteries, and by the formation of vessels with muscular and elastic coats within this tissue. But the inflammation was still active: patches of infiltration with lymphocytes, plasma cells, and eosinophil leucocytes lie in the pleura and in the interstitial tissue of the lung; the lumen of some pulmonary arteries is occupied by young granulation tissue.

Although no *S. pallida* have yet been found there can be no doubt in view of the histology that the inflammation of the lung, pleura, and pulmonary arteries was, like the inflammation of the testicles, syphilitic. If confirmation were required it can be found in the positive Wassermann reaction, the perforation of the palate, the fibrosis of the tonsils, and the scar on the penis, which at least suggests venereal infection. The syphilitic inflammation of the lung is entirely interstitial; there is no trace in the sections of bronchiolitis obliterans or of intra-alveolar organisation. Further, there is no evidence of its having spread fan-wise from the hilum into the lung.

In most of the pulmonary arteries in the lung that were free from inflammatory endarteritis, in the right primary branch of the pulmonary stem, and in the pulmonary stem itself there was intimal hypertrophy; and the hypertrophied intima was the seat of considerable atheroma. Such intimal hypertrophy and secondary degeneration occur in all cases of obstruction to the flow of blood in the lesser circulation, for instance in mitral stenosis; and they have been in my experience proportional to the *estimated* degree of obstruction.

THE RESISTANCE TO MALIGNANT GROWTH.

BY TREVOR HEATON, D.M. OXF.,
STUDENT OF CHRIST CHURCH, OXFORD.

IN the following paper a brief résumé is given of the results of seven years' work, of which a full account has been already published elsewhere.[1]

The experiments were prompted in the first instance by a doubt whether the cancer cell differs in any essential respect from cells of the normal body. The extreme diversity of cancer, it seemed, is difficult to reconcile with the idea of a specific nature or common causation; and the gradation of its different types from innocent tumours to malignant disease of the most virulent kind points to a perfectly regular descent from one to the other. The histological classification of tumours is notoriously artificial: their propensity when malignant to invade adjacent tissues, to form metastases, or to survive transplantation may be very pronounced and quite distinct as a general rule, but on the other hand is sometimes only feebly developed or even altogether absent; it is scarcely possible to look upon any of these properties singly as absolutely characteristic or fundamental, and the combination of them all is probably rather exceptional. The boundaries between tumour tissue and normal cells are almost as indefinite as those between one tumour and another: three well-known illustrations of this are the dermoid cyst, an evident anomaly of development; the chorion, passing occasionally into chorion-epithelioma; and embryomata, or the tumours which arise from the introduction of embryonic fragments into the tissues of an adult host. The course of evolution rarely leaves behind it so complete a chain of "missing links" between the various products of its operations. Finally, the application of a series of tar products of varying potency may induce hyperplasia, or papilloma, or cancer, or all of these in succession; and the cancer when it develops may or may not prove to be transplantable.

The growth of cancer was for these reasons regarded as of fundamentally the same nature as growth of any other kind, however magnified and distorted and nearly unrecognisable the growth-picture may become. In this connexion the word "growth" is itself ambiguous; for the growth of a tissue must be differentiated from the growth, or condition of multiplication, of its constituent cells. The growth of a cell-population is not merely a question of birth-rate; it is a preponderance of births over deaths. In the normal adult body there is, as a rule, no such preponderance, and therefore no growth; but this is not because there is no cell-multiplication, but because there is an equally high cell-mortality. Even in old age the cells of many tissues continue to multiply rapidly; and the characteristic feature of a tumour is not that its cells multiply, but that their multiplication leads to uncontrolled growth. In the genesis of cancer, therefore, it seemed to be idle to consider only the cancer cell; and necessary first to ascertain the normal method of growth control. For if the transitional stages in tumour malignancy reflect different degrees of failure in the control process, they indicate also that the method of control is seldom if ever completely ineffective. Moreover, if the process of physiological control were understood, it might also be reinforced; and the prevention or even the arrest of malignant disease might in fact be accomplished, not by pharmacological methods in the narrow sense, nor by the methods of bacteriological immunisation, but by the physiological method at work in the normal body for the prevention of excessive growth, of which cancer itself is only an extreme and perverted form.

The Control of Normal Growth.

Leaving aside for the moment, therefore, all question of tumours, the conditions first to be reviewed are those which prevail in the normal body.

Tissues which *fail to increase*, though their cells proliferate, must clearly be subject to some form of restraint, and the process has been described as "tissue tension." It is a description, not an explanation, and implies only that tissues in contact with one another maintain a certain equilibrium, in spite of tendencies to expand which any of them may display. But the manner of this resistance to expansion would not seem to be in doubt, though the blood-cells and blood-forming organs are obviously exceptional, and require control of an exceptional kind. Apart from these, any tissue whose cells are constantly multiplying will expand, like other living colonies, to the limit of the available food-supply, and tissue tension must involve the restriction of this supply. The needs of different tissues in this respect no doubt vary greatly, and include nutrition, oxygen, mechanical support, and the removal of waste products; but so long as these services, comprised under the name of "stroma," are stationary, all tissues dependent thereon must be stationary also. It is therefore striking that most of the tissues whose cells continue to multiply throughout life are epithelia, while the vascular connective tissues are normally static and passive. If growth never occurred the process of tissue tension might be thought to consist simply in this passivity, imposing a limit on epithelial proliferation and differing in various *localities* only in the pattern of the various supporting and proliferative tissues.

Actually growth is always taking place; almost every organ is capable of hypertrophy and of renewal of activity for the repair of injury. In the skin, for example, the multiplication of epidermal cells is normally limited to the replacement of wear and tear, any increase being prevented by the unyielding character of the underlying stroma; but sometimes true growth occurs, as when hairs are developed at puberty or, as in many animals, with the recurrence of the seasons. In such cases the hair follicles increase in size, in response to the stimulus of a hormone; and this involves growth not only in the specific epithelium, but also in the connective tissue which supports it. The hormone acts directly upon the epithelium, but this in turn induces a reactive increase of stroma. The passivity of stroma, therefore, is only relative; it is overcome whenever the growth tendency of the epithelium receives *additional* impetus. Similar reactivation of static connective tissue is seen on a large scale in the process of granulation, and in both cases passivity is resumed as soon as the special conditions cease to exist.

An accurate balance, therefore, preserves the passive status of connective tissue stroma, and on this equilibrium tissue tension would seem to depend. The stimulus of epithelial activity tends constantly to upset the equilibrium, but is only in special circum-

stances sufficient to do so. There must be some agency to counteract it; it cannot be counteracted merely by the inherent inertia of connective tissue. For connective tissue has, in fact, no such inherent inertia at all; when cultured in vitro its cells continue to proliferate indefinitely, and indeed with greater robustness than any other type of cell. The influence which antagonises the stimulant action of epithelia is therefore external; and on the analogy of the numerous growth-promoting factors which are known, both hormones and vitamins, is likely to have a chemical character. It is likely, in fact, to be a hormone or a vitamin itself, the equilibrium of tissue tension being of the common physiological type, between this factor which tends to arrest growth and antagonistic factors tending to promote it; now one predominates, now the other. Furthermore, the growth-promoting influences are multiple, for the epithelia upon which they act are very diverse; but the inhibiting influence which acts upon a single tissue, the stroma, is not unlikely to be single.

A Growth-inhibiting Factor.

Various organs were therefore tested in the hope of obtaining an extract with the property of stabilising connective tissue. The method employed was that of tissue culture, the extracts being added to a nutrient medium in which connective tissue cells (fibroblasts) were implanted; implants of epithelia (from the intestine) were made at the same time as a control, to ensure the general fitness of the medium for cell growth. Nor was the search long or difficult. The extracts were made in 75 per cent. alcohol, evaporated down, taken up in water and sterilised, being freed thereby from proteins and growth-promoting factors which all tissues, of course, contain; and the action in question was shown by all the tissues examined in approximately the same degree, extracts of the liver being perhaps rather more active than those of other organs. In the plain medium, that is to say, fibroblasts and epithelial cells grew equally well; but the addition of extract of any tissue prevented the growth of the fibroblasts without interfering with that of epithelia.

The widespread distribution in tissues of a substance which inhibits growth was not unexpected; but it seemed to point to derivation from the diet rather than to a synthetic origin in the body, and yeast, among other foodstuffs, was tested for its presence. Brewers' yeast was found to contain it, but not bakers' yeast, and a likely source was thus indicated in malt, upon which brewers' yeast is grown. After long use of an extract obtained from yeast, malt was accordingly substituted, and seemed to be preferable, yielding very readily a crude but active extract of fairly constant composition.

Effect on Normal Growth.

An extract being now available with the desired action upon connective tissue cells in vitro, the next step was to apply it in vivo. The suggestion was that this substance inhibits the proliferation of fibroblasts in the body and determines, by its eventual predominance, the cessation of the growth period. If this were so, it seemed that by administration of the extract to young animals the growth-promoting factors might be prematurely counteracted and normal growth cut short. It was administered by addition to the water in the case of aquatic animals, and by intraperitoneal injection to mammals. The effect was noted on the metamorphosis of tadpoles, on the regeneration of amputated parts in newts, on the growth of young rats, guinea-pigs, and rabbits, and on the course of pregnancy in guinea-pigs. The result in every case was the same: with small doses growth was delayed, with larger doses it was completely and immediately arrested; and when the treatment was omitted growth was resumed.

Objection might be made that the effect of injecting a crude extract would be gross poisoning, and arrest of growth from mere interference with appetite and general well-being. Indeed the objection would not be unreasonable, for the doses given were but little less than lethal. It was noticed, however, that the younger the animals the less easily were they affected. The relative dose for a small rat or guinea-pig was three times as large as that required for a half-grown animal; and a curve was obtained in the case of guinea-pigs showing a definite inverse ratio between body-weight and the dose per kilo necessary to arrest growth. So marked a discrepancy, it seemed, would scarcely be consistent with a merely toxic effect; but was only to be expected if the action were specifically upon the growth process, for the energy of growth is at its greatest in young animals. Furthermore, the dose necessary to arrest growth was found to be considerably larger than was sufficient to prevent its resumption, and the dose necessary to arrest the course of pregnancy considerably larger than would be tolerated by non-pregnant animals.

Effect upon Tumours.

The normal function of this factor, it is suggested, consists in preserving the balance of physiological growth, and as such may have some general physiological interest in relation to problems of growth and diet. But its effect when given in excess would seem to be applicable also to the case of growing tumours. For as seasonal or other normal growth is induced by hormones, the growth of tumours is induced by epithelial stimulation in other ways, as by certain irritants; and the effect in either case is to overcome the resistance to expansion of the underlying stroma. If by giving the inhibiting extract in excess this resistance can be raised sufficiently to prevent physiological growth, there would seem to be no reason why the growth of tumours whose demand for stroma is precisely the same should not be resisted in the same way.

Whether the inhibiting extract will be found in fact to have any prophylactic or curative value as applied to human cancer has yet to be determined, and experiments to that end are in progress. Hitherto trial has been made only with transplantable tumours in rats—namely, the Jensen rat sarcoma, and, in a few cases, the rat carcinoma No. 9—and the extract has necessarily been given by intraperitoneal injection. The results were striking enough, tumour growth in several hundred animals being brought very rapidly to a standstill; but the necessary dose was large, since only young rats were used, and after the growth of their tumours had been arrested the animals usually died. The difficulty was thought to be only technical, for in a number of rats which could be induced to take the extract by the mouth complete retrogression of the tumours was obtained. The following facts, moreover, seemed to be of importance: (1) the appearance of the tumours after arrest of growth was one of intense venous congestion, as has been found also after their arrest by radium or the application of heat; (2) whatever the size of the animal the dose necessary to arrest tumour growth was the same as that necessary to arrest its body growth, and in full-grown animals would therefore be comparatively small; (3) an effect on tumours was only obtained with extracts which proved on tissue cultures to exhibit the specific property described, of preventing the growth of fibroblasts.

The Jensen rat sarcoma is no less malignant than the majority of spontaneous tumours; and the experiments therefore suggest that the differences between malignant and normal cells are less important than their fundamental resemblance. A tumour, like any other growing focus, needs a growing vascular environment; it is on this environment that the control of normal growth is exerted, and it is here that resistance may be offered also to the growth of cancer. The inhibiting factor seems to provide a possible agent for making this resistance effective.

Corrigendum.—In Dr. E. Fränkel's article on the Blastogenic Principle in Fowl Sarcoma, THE LANCET, Sept. 14th, p. 539, col. 2, line 50, for "six attempts out of ten" read "out of *twenty-one*."

THE USE OF INSULIN IN THE TREATMENT OF PERNICIOUS ANÆMIA.

By Dr. L. von Varga,

ASSISTANT AT THE MEDICAL CLINIC OF THE ROYAL HUNGARIAN FRANZ-JOSEPH UNIVERSITY, SZEGED (PROF. DR. M. FANCSÓ).

The importance of liver in the process of blood-regeneration was first pointed out, independently, by Whipple and Robscheit-Robbins, and by Jeney. Whipple and his collaborator were the first to report good results from feeding dogs, made anæmic by repeated bleeding, with fresh liver, while the favourable results of protein-free liver-extract were first published in a Hungarian medical journal by Jeney in a communication from the Jobling Institute for Pathology, Columbia University, where he carried out his researches in 1923–24. The paper[1] by Whipple and Robscheit-Robbins was published in May, 1925, and Jeney's work appeared in the spring of the same year.[2] Minot and Murphy in 1926 introduced their successful liver diet, which has since become famous, for pernicious anæmia, but Whipple and his collaborator adopted liver extracts only in 1927. Jeney's researches, performed in 1923–24, partly in collaboration with Prof. Jobling, were therefore the first in connexion with a protein-free liver extract. Accounts of them were published in America in 1927.[3] [4] I have emphasised these facts because Jeney's right of priority is in question, and his name is not mentioned in the most important papers and works on the subject. Mouzon[5] alone mentions the experiments of Jeney and Jobling with alcoholic liver extract.

Liver and Insulin.

Of the very numerous proposals for treating pernicious anæmia that represented by Minot and Murphy seems to be the most noteworthy. According to these investigators, liver supplies the materials necessary for building up the cytoplasm of the blood corpuscles and at the same time has a stimulating influence on the bone-marrow, acting in so specific a manner that they consider that any anæmia in which a liver diet is ineffective may be excluded from the class of pernicious anæmia. That liver actually contains substances which promote the formation of red blood corpuscles—in the form of building substances or specific stimulants—is proved by the researches of Jeney and Jobling and by Robscheit-Robbins and Whipple's experiments on animals. Jeney's[6] work shows that the substances promoting blood formation are to be sought in the decomposition products of red blood corpuscles developed in the liver.

It is only natural that the treatment of pernicious anæmia should depend on a series of factors, such as the state at which the patient is received for treatment, his individuality, his reactivity, the regenerative power of the bone-marrow, the duration of the malady and the number of relapses, and this fact must not be disregarded. It explains the relative failures frequently obtained alongside favourable results.

During the past two years we have had a strikingly large number of cases of pernicious anæmia in comparison with former years. Since the essential of treatment must lie in assisting the blood-forming organs and in strengthening the whole body, we thought it advisable to employ a remedy intended to combat the [illegible] known loss of appetite in pernicious anæmi[illegible]s purpose tried insulin, which we had [illegible] using in all cases of anorexia. [illegible]hexia of our patients made it [illegible] liver diet at once, but we hoped [illegible] their appetite so that they [illegible] time we had eight patients [illegible]tment and its effects is

Case 1 was treated with insulin alone (60 units daily) and the number of the red blood corpuscles rose within a month from 770,000 to nearly four millions, the appetite being meanwhile excellent, while the hæmoglobin content also assumed more normal figures. Cases 2, 3, and 4, which were placed on insulin and arsenic treatment, showed results in no way better than Case 1. The rise in the blood count was somewhat gradual, the hæmoglobin values showing rather greater improvement. Case 5 is interesting. During the first 24 days of treatment the patient received 30 units of insulin daily and 1 c.cm. of strychnotonin (a preparation containing arsenic). During this period the red blood cells rose from 850,000 to 1,400,000, and the hæmoglobin percentage from 22 to 28. The patient was then put on a diet including 100 g. of cooked calf's liver daily, with the result shown in the table. Case 6 received 60 units of insulin daily from the first to the 37th day, and 2·5 g. of Richter's perhepar (a liver extract) from the 10th to the 50th day. During the first ten days, with insulin alone, there was no increase in the blood count and hæmoglobin values, though the general condition and appetite were excellent. When liver treatment was started they immediately began to rise, and after a month the patient was discharged in very good health. Case 7 at first responded well to insulin and arsenic treatment, but after a month's progress the red cells and hæmoglobin became stationary. From the 80th day onwards the insulin was stopped and the patient was given 100 g. of Schottmüller's hepatopson daily. It was very striking to note that the number of the red corpuscles increased by 1·5 million during the ensuing 20 days, while the hæmoglobin value declined. In Case 8, owing to the grave condition of the patient, both insulin and liver extract were given from the beginning (insulin 50 units and a spoonful of hepatopson). Both forms of treatment were discontinued within 42 days, but in two months the number of the red corpuscles rose to over five million, although the patient was in a dying state when admitted.

No.	Age in years.	Period of treatment.	Values at the beginning and at the end of treatment.			Daily increase.	
			Hb %.	Blood count in millions.	Colour-index.	Hb.	Blood count.

8	36	Jan. 6 to Mar. 21.	21–75	0·73–4·4	1·02–0·70	0·71	45,655

Treatment.—(1) 2100 units insulin; (2) 540 units insulin and strychnotonin; (3) 3000 units insulin, and arsenic; (4) 2200 units insulin, and natrarsen; (5) 690 units insulin, 4600 g. liver; (6) 2220 units insulin, 100 g. perhepar; (7) 4050 units insulin, 2100 g. hepatopson; (8) 1950 units insulin and 3000 g. hepatopson.

The subjective condition improves in a very short time in response to insulin by itself, as well as to the insulin-liver and insulin-arsenic treatments. After taking insulin bulimia sets in, and the vertigo, buzzing in the ears, and general debility disappear; the condition of the patients visibly improves, and the number of red corpuscles and the hæmoglobin content increase (*by 30,000–40,000 and 5·10 per cent. respectively per day*). The headaches disappear last, but these, together with serious anæmia, are correlated

1927, xxi., 5

with the gastro-intestinal disorders, which, as a rule, remain to the end and which are often strongly marked. The constant anorexia can be transformed into bulimia in three or four days by insulin, so that patients want to eat continuously. Return of healthier colour may be looked for on the tenth day; this and the redness of the lips is increasingly pronounced. As the blood count and hæmoglobin values rise there is a fall in the colour-index, and a disappearance of hyperchromatosis, together with a decrease of anisocytosis, megalocytosis, and poikilocytosis, and disappearance of polychromatophilia and normoblastosis. The only symptom which remains to the end, and which it is impossible to influence in any way, is achlorhydria.

I began the insulin treatment with 20–30 units (twice daily), increasing with the improvement in appetite to 40 units, always half an hour before meals. With the use of Richter's insulin there are practically no disagreeable symptoms, such as hyperæmia, œdema, and pains. Large doses, however, entirely destroy the appetite, while there is also the danger of hypoglycæmia. It should be noted that in general the insulin treatment has always an optimal limit. In Case 8 we discontinued the liver diet, mainly because the hepatopson was very trying to the patient, owing to its bulk and unpleasant smell. Later we had recourse to Richter's perhepar, a remedy containing a large quantity of liver substance in quite a small compass (1 g. equivalent to 100 g. of liver), so that the daily dose of 250–300 g. of liver can be administered in the form of a few grammes in wafers without any difficulty. *It is now obtainable also in tablet form.*

Results of Other Workers.

I thought the publication of these results with insulin would not be without interest, if only because Walinski[7] has hitherto been the sole investigator who has reported satisfactory results from a combined insulin and arsenic treatment with blood transfusion, though Weil[8] has also had a certain degree of success with the same combination. He, however, gave only 5–10 units of insulin. Rathery[9] has reported unfavourable results, and Neuburger,[10] who made unsuccessful experiments in 1924, rejects insulin treatment not merely because the patients are apprehensive of its unpleasant effects, but also because he found that in every case there was pronounced deterioration. According to Imchanitzky, the number of red corpuscles decreases with insulin. Lévai[11] also mentions experiments by Jaksch-Wartenhorst, according to which the use of insulin in pernicious anæmia causes a deterioration in the condition. Varga[12] alone reports the case of a man of 70 in which insulin and arsenic treatment gave good results.

When it is considered that many authorities regard the cause of pernicious anæmia as being a displacement of the blood reaction in the direction of acidosis, which facilitates hæmolysis, and that insulin, on the other hand, increases the alkalinity of the blood (Walinski), the soundness of the insulin treatment appears to be further confirmed.

In a case like No. 8 the use of insulin is of vital importance. On his admission the patient was unconscious, the number of red blood corpuscles being 700,000. Every attempt to feed him failed. After an insulin injection, however, he even took hepatopson, although he fell asleep while being fed. On the third day he began to have a keen appetite, his complexion soon became more healthy, and in a fortnight he was able to leave his bed for a few minutes.

Whilst a liver diet must be regarded as the standard remedy for pernicious anæmia, insulin may be looked on as an indispensable auxiliary.

Clinical and Laboratory Notes.

LOA LOA INFECTIONS.

A CASE WITH RAPID ONSET OF SYMPTOMS.

By N. A. Dyce Sharp, M.R.C.S. Eng.,
MEDICAL OFFICER, WEST AFRICAN MEDICAL STAFF.

Attention has often been drawn by Low, Manson-Bahr, and others to the longevity of *L. loa*, and to the lengthy period which may elapse before either symptoms or infection of the blood by filarial embryos becomes manifest. This period may amount to four or more years, and worms have been removed from beneath the conjunctiva of persons who have been outside an infective area for 12 and even 15 years.

On the other hand, little attention has been paid to the minimum period which must necessarily elapse between the bite of the infected chrysops and the moment when the first symptoms appear. The principal symptom, apart from pain and discomfort in the eye when a mature worm happens to pass across it beneath the conjunctiva, are certain rather odd enlargements known as Calabar swellings which most commonly affect the forearms and wrists but also occur in the legs, trunk, and face, and even under the scalp. In an endemic area their appearance is so characteristic as to make the diagnosis comparatively simple in almost every case. Often they arise in a night, giving a bloated, œdematous appearance to the affected part. While objectively they exhibit many of the signs of an acute inflammatory condition, the subjective sensations are relatively trivial, and in a large proportion of cases there is no actual pain or tenderness, but merely stiffness with a feeling of weakness. They never lead to suppuration, and as a rule they disappear as mysteriously as they arise in 50 to 70 hours.

We are at present very far from knowing their true pathology. Manson, who described the worm in 1891, believed that they might be caused by the emission of myriads of larvæ by the pregnant female lying in the connective tissue. Others have suggested as a cause the death of the mature worm and the setting free of unknown toxins. It is proposed to show that in the light of the case given below both these theories are untenable.

Filaria loa is manifestly long-lived and, according to Manson-Bahr, development of the larva in the human body is so slow that full maturity is not reached for several years. In support of this statement he points to the well-established fact that the offspring of the worm may not appear in the blood as microfilariæ for seven years, while the adult parasite itself may not appear for four or more years. Further, infected children rarely show embryos in the blood though immature worms may be found in the tissues. *These facts would lead one to expect a period of several years at least to elapse between the date of infection and the appearance of Calabar swellings if the latter are caused by mature or parturient filariæ.*

THE USE OF INSULIN IN THE TREATMENT OF PERNICIOUS ANÆMIA.

BY DR. L. VON VARGA,
ASSISTANT AT THE MEDICAL CLINIC OF THE ROYAL HUNGARIAN FRANZ-JOSEPH UNIVERSITY, SZEGED (PROF. DR. M. FANCSÓ).

THE importance of liver in the process of blood-regeneration was first pointed out, independently, by Whipple and Robscheit-Robbins, and by Jeney. Whipple and his collaborator were the first to report good results from feeding dogs, made anæmic by repeated bleeding, with fresh liver, while the favourable results of protein-free liver-extract were first published in a Hungarian medical journal by Jeney in a communication from the Jobling Institute for Pathology, Columbia University, where he carried out his researches in 1923–24. The paper[1] by Whipple and Robscheit-Robbins was published in May, 1925, and Jeney's work appeared in the spring of the same year.[2] Minot and Murphy in 1926 introduced their successful liver diet, which has since become famous, for pernicious anæmia, but Whipple and his collaborator adopted liver extracts only in 1927. Jeney's researches, performed in 1923–24, partly in collaboration with Prof. Jobling, were therefore the first in connexion with a protein-free liver extract. Accounts of them were published in America in 1927.[3] [4] I have emphasised these facts because Jeney's right of priority is in question, and his name is not mentioned in the most important papers and works on the subject. Mouzon[5] alone mentions the experiments of Jeney and Jobling with alcoholic liver extract.

Liver and Insulin.

Of the very numerous proposals for treating pernicious anæmia that represented by Minot and Murphy seems to be the most noteworthy. According to these investigators, liver supplies the materials necessary for building up the cytoplasm of the blood corpuscles and at the same time has a stimulating influence on the bone-marrow, acting in so specific a manner that they consider that any anæmia in which a liver diet is ineffective may be excluded from the class of pernicious anæmia. That liver actually contains substances which promote the formation of red blood corpuscles—in the form of building substances or specific stimulants—is proved by the researches of Jeney and Jobling and by Robscheit-Robbins and Whipple's experiments on animals. Jeney's[6] work shows that the substances promoting blood formation are to be sought in the decomposition products of red blood corpuscles developed in the liver.

It is only natural that the treatment of pernicious anæmia should depend on a series of factors, such as the state at which the patient is received for treatment, his individuality, his reactivity, the regenerative power of the bone-marrow, the duration of the malady and the number of relapses, and this fact must not be disregarded. It explains the relative failures frequently obtained alongside favourable results.

During the past two years we have had a strikingly large number of cases of pernicious anæmia in comparison with former years. Since the essential of treatment must lie in assisting the blood-forming organs and in strengthening the whole body, we thought it advisable to employ a remedy intended to combat the [illegible] own loss of appetite in pernicious [illegible] s purpose tried insulin, which we [illegible] using in all cases of anorexia. [illegible] hexia of our patients made it [illegible] ver diet at once, but we hoped [illegible] their appetite so that they [illegible] time we had eight patients [illegible] tment and its effects is

Case 1 was treated with insulin alone (60 units daily) and the number of the red blood corpuscles rose within a month from 770,000 to nearly four millions, the appetite being meanwhile excellent, while the hæmoglobin content also assumed more normal figures. Cases 2, 3, and 4, which were placed on insulin and arsenic treatment, showed results in no way better than Case 1. The rise in the blood count was somewhat gradual, the hæmoglobin values showing rather greater improvement. Case 5 is interesting. During the first 24 days of treatment the patient received 30 units of insulin daily and 1 c.cm. of strychnotonin (a preparation containing arsenic). During this period the red blood cells rose from 850,000 to 1,400,000, and the hæmoglobin percentage from 22 to 28. The patient was then put on a diet including 100 g. of cooked calf's liver daily, with the result shown in the table. Case 6 received 60 units of insulin daily from the first to the 37th day, and 2·5 g. of Richter's perhepar (a liver extract) from the 10th to the 50th day. During the first ten days, with insulin alone, there was no increase in the blood count and hæmoglobin values, though the general condition and appetite were excellent. When liver treatment was started they immediately began to rise, and after a month the patient was discharged in very good health. Case 7 at first responded well to insulin and arsenic treatment, but after a month's progress the red cells and hæmoglobin became stationary. From the 80th day onwards the insulin was stopped and the patient was given 100 g. of Schottmüller's hepatopson daily. It was very striking to note that the number of the red corpuscles increased by 1·5 million during the ensuing 20 days, while the hæmoglobin value declined. In Case 8, owing to the grave condition of the patient, both insulin and liver extract were given from the beginning (insulin 50 units and a spoonful of hepatopson). Both forms of treatment were discontinued within 42 days, but in two months the number of the red corpuscles rose to over five million, although the patient was in a dying state when admitted.

2	30	Apl. 20 to May 26	28–78	1·14–2·9	1·11–1·21	1·4	48,0[illegible]
3	55	Feb. 6 to Mar. 17.	35–70	1·4 –3·2	1·13–0·98	0·87	45,9[illegible]
4	55	Mar. 27 to June 5.	48–70	1·36–2·50	1·55–1·23	0·3	16,511
5	41	July 27 to Oct. 1.	22–65	0·85–4·5	1·23–0·65	0·59	50,5[illegible]
6	66	Apl. 16 to June 5.	36–82	1·8 –3·9	1·00–1·05	0·92	42,0[illegible]
7	36	Dec. 1 to Mar. 13.	37–80	1·8 –4·9	0·70–0·80	0·6	41,318
8	30	Jan. 6 to Mar. 21.	21–75	0·73–4·4	1·02–0·76	0·71	45,555

Treatment.—(1) 2100 units insulin; (2) 540 units insulin and strychnotonin; (3) 3000 units insulin, and arsenic; (4) [illegible] units insulin, and natrarsen; (6) 690 units insulin, 4000 g. liver; (6) 2220 units insulin, 100 g. perhepar; (7) 4050 units insulin, 2100 g. hepatopson; (8) 1950 units insulin and 3000 g. hepatopson.

The subjective condition improves in a very short time in response to insulin by itself, as well as to the insulin-liver and insulin-arsenic treatments. After taking insulin bulimia sets in, and the vertigo, buzzing in the ears, and general debility disappear; the condition of the patients visibly improves, and the number of red corpuscles and the hæmoglobin content increase (by 30,000–40,000 and 5·10 per cent. respectively per day). The headaches disappear last, but these, together with serious anæmia, are correlated

Jo
k-R
Roy. S
F., Ha
, xxi., 5

changes and no difficulty in swallowing were noted. On aspiration of the left chest 5 c.cm. of clear fluid were obtained. This contained a large amount of albumin, erythrocytes, and occasional polymorphonuclear and some mononuclear cells, but no tubercle bacilli. Cultures were sterile, as was also the blood culture. The sputum contained no tubercle bacilli or streptococci and little pus. A blood count showed 5,744,000 red cells and 6148 white cells made up of: polymorphonuclear cells 70 per cent., lymphocytes 22 per cent., and large mononuclears 8 per cent. The colour-index was 0·7 and the hæmoglobin 80 per cent.

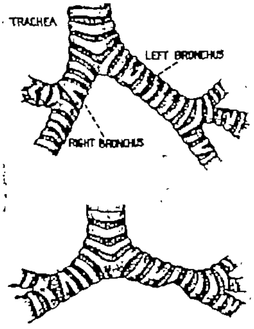
A diagnosis of collapse of the lower lobe of the left lung was made.

On June 18th the signs were as before and included a few coarse crepitations at the base of the left lung. Later signs of gross congestive failure appeared. Digitalis and leeches were ordered, but on July 9th the patient died.

Autopsy by DR. KEITH.

The general development was normal for the age. There were a few recent pleural adhesions on both sides, and some *small* patches of partly organised *lymph. The right* lung was intensely œdematous and congested, and showed a recent infarct at the apex of the right lower lobe, covered by a patch of pleurisy. The changes in the lung were recent and did not suggest a broncho-pneumonia. The lower lobe of the left lung was collapsed; not to that extreme degree seen in pneumothorax, but it was completely airless and no fluid could be expressed from it. The upper lobe was very slightly congested. The aorta and œsophagus appeared normal and healthy. The trachea contained much mucus but was otherwise healthy. On opening the posterior surface of the left bronchus a large blood-clot was found. This proved to be the contents of the left auricle, which was very greatly enlarged and had come into relation with the posterior surface of the left bronchus. Further examination of the left bronchus showed that there was—at about ¼ inch beyond the original bifurcation of the bronchus—a definite kinking, the kink being at the point where the left auricle had been pierced while opening the bronchus. *There was evidence of a* considerable degree of obstruction at that point, although the removal of the organs from the body had partly reduced it. The right bronchus was normal.

FIG. 2.

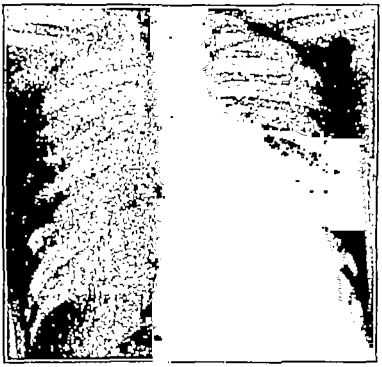


Anterior view of trachea and bronchi. Above: normal condition. Below: widening of interbronchial angle.

The heart was greatly enlarged and weighed 15 oz. In situ there was marked enlargement to the left, fullness in the pulmonary area, and slight enlargement to the right. The pericardium contained half a teacupful of fluid. There was a patch of pericarditis over the apex, which was united to a corresponding patch on the parietal pericardium by a thin fibre ¼ inch long. The right auricle was slightly enlarged. The left auricle was very markedly enlarged upwards and to the left, and contained a large clot of blood. The exact size could not be made out. The right ventricle was slightly enlarged. The left ventricle was markedly enlarged and its walls much thickened. No gross valvular disease was present. The mitral valve was widened. In the fresh specimen three fingers and in the hardened specimen two fingers could be passed through the mitral orifice with ease. The mitral valve was thicker than normal and showed some roughening at its edge. The chordæ tendinii were definitely shortened and thickened. The aortic, tricuspid, and pulmonary valves appeared competent and normal in structure. There was some free fluid in the abdomen, and the liver and spleen showed evidence of congestive failure.

The clinical picture was one of active rheumatic carditis. The clinical signs of persistent tachycardia, frequent extrasystoles, and at one time a continued ventricular rate of 100 per minute, unaffected by exercise or change of posture and possibly constituting evidence of auricular flutter, suggested particular involvement of the auricular musculature in the *disease process. The physical signs were those typical* of mitral stenosis, especially the localised apex-beat, the diastolic thrill, and the full diastolic and systolic bruits. The terminal signs denoted left ventricular failure. The *radioscopic* appearance in the antero-posterior view was that of mitral stenosis. Unfortunately with the technical facilities at our disposal an oblique view could not be taken.

FIG. 3.



Radiogram showing enlargement of the left auricle.

At autopsy the picture was that of rheumatic carditis; a large heart with a wide but thickened mitral orifice, showing no evidence of mitral stenosis, and a very large left auricle. This is an association which I have never seen and to which there is no reference in the literature. A large left auricle is invariably described in association with mitral stenosis, and is exemplified by the cases described by various clinicians. The radiological appearance of "mitral stenosis" was shown although at autopsy stenosis of the mitral valve was not present. Collapse of the lower lobe of the left lung due to constriction of the bronchus by the pressure of a large left auricle—*as in this case—is rare.*

Our thanks are due to Dr. Remington Hobbs for permission to publish this case.

THE MENTAL FACTOR IN BRONCHIAL ASTHMA.

REPORT ON TWO CASES.

BY M. K. EL KHOLY, M.R.C.S. ENG., D.P.M.,
SENIOR MEDICAL OFFICER, ABBASIA MENTAL HOSPITAL, CAIRO.

THE following notes demonstrate the important part which a mental factor may play in the causation of bronchial asthma:—

CASE 1.—The patient was a married youth, aged 27. When seen in November, 1926, he had been suffering from almost daily attacks of the disease for 18 months and his condition had been diagnosed as bronchial asthma by three of the leading physicians in Cairo. The disease started with daily attacks of panting which used to come on in the morning half an hour after leaving bed; they lasted about two hours each and were accompanied by profuse sweating, running from nose, and coughing with bringing up of phlegm. The attacks increased in severity and two months later the patient began to wake up suddenly about 2 A.M. with a feeling of suffocation, dyspnœa, wheezing in the chest, cough, expectoration, sweating, and coryza. After treatment by different doctors for a year the attacks became within seven hours of the onset of otitis, but that did not prevent his having to operate later for severe mastoid disease. In some cases it was not safe to wait a week after incising the drum before operating on the mastoid. It was a good working rule to hold one's hand for about five days; whether the mastoid operation should be done earlier depended on whether the patient was very toxic. A good rule was that if the deep part of the meatus sagged the mastoid must be opened. He did not intend to deal with the chronic ear on this occasion. The cessation of an ear discharge was sometimes due to the bursting of a bulla. He did not pin his faith to any particular material for swabbing and syringing the ear. In cases which were painful syringing should be deferred for a few days. For incising the drum he now always used a general anæsthetic. He did not think the wrong method of blowing the nose caused otitis media; if the drums were intact when the nose was blown, infective material could not be injected along the Eustachian tube and into the ear. The routine use of gargles and snuffles was a matter which did not come into his experience; medical officers of schools were themselves in a position to supply valuable information on those points. He had ordered leeches only once in 25 years; he did not favour their use.

ROYAL SOCIETY OF MEDICINE.

SECTION OF THERAPEUTICS.

A MEETING of this Section was held on Oct. 8th, when Dr. P. **HAMILL** delivered a presidential address entitled

SOME PRINCIPLES OF THERAPEUTICS.

He pointed out that an accurate appreciation of the underlying conditions is essential as a basis for rational treatment. Departures from the normal physiology may be but manifestations of compensatory processes and attempts at "correction" are not then helpful but may hinder recovery. A high blood pressure may be necessary in a given case; nitrites will then be harmful. Antipyretics are little used in fever nowadays; on the contrary fever, artificially induced, may even be beneficial, for example in the treatment of general paralysis by malaria, and in those conditions which are improved by protein shock therapy. Many conditions which call for treatment are the result of previous illness. Damaged organs must be sustained and protected from further injury, and here lies the importance of eradicating septic foci—e.g., the removal of infected tonsils in rheumatic heart disease. Where part of a gland of internal secretion has been destroyed, the effects of the loss may sometimes be circumvented if its active substance can be isolated and easily administered; thyroid gland or thyroxin given for myxœdema, and insulin for diabetes, are good examples. Disorders of infective origin well illustrate therapeutic principles, for elimination of the cause lies for the most part within the sphere of preventive medicine. In the therapeutic sphere direct attack on organisms within the body has been made with success in many protozoal infections—e.g., malaria and amœbic dysentery. Organic arsenic preparations have proved valuable in syphilis and relapsing fever, and antimony compounds in leishmaniasis. In bacterial infections direct attack has been less fruitful; urinary antiseptics and mercurochrome are but partial successes, but the results obtained with sanocrysin in tuberculosis and chaulmoogra in leprosy augur well for the future of chemotherapy. To confer or exalt immunity is perhaps the ideal method of coping with infection if the cause cannot be eliminated or directly combated. Prophylactic immunisation and serum therapy have been very successful in many infections, but fail to fulfil all demands, owing to their inherent specificity, and in some cases owing to the brief duration of the immunity conferred. We have as yet no Mithridatium. For many infections immunising agents of sufficient potency have not yet been developed, and the body must, therefore, rely on its own powers of resistance.

To raise resistance to a high pitch and maintain it there should be our constant aim. Can it be said that adequate attention is devoted to the problems involved? Nutrition, elimination, rest, and general hygiene are the foundations on which resistance to infection and the power of developing immunity are based. Observations by Edward Mellanby and his colleagues indicate that deficiency of vitamin A in the dietary lowers resistance to infection in experimental animals, and a generous supply of this vitamin to patients with puerperal septicæmia is said to have lowered the mortality to zero in a series of cases. In a London business house during the influenza epidemic of the early part of this year a preparation rich in vitamins was supplied to those who desired to take it. There was hardly an absentee owing to influenza or "cold" amongst those who availed themselves of the offer. The conclusion that diet is a large factor in controlling resistance to infection and the development of immunity may fairly be drawn, and the complete proof of this proposition will be a therapeutic advance of the first magnitude. The consumption of milk, dairy products, and oily fish in this country is far too small; incidentally, advocacy by the medical profession of dietary improvement will benefit agriculture as well as the health of the community. Rest is still underrated as a factor in treatment. The widespread use of hypnotics is disquieting; the avoidance of the necessity for their use is desirable. In spite of the importance of quiet, especially for the sick, hospitals and nursing homes still mention the fact that "trams pass the door" as a recommendation rather than a drawback. The rebuilding of hospitals in the inner zones of large towns is surely not consistent with the requirements of rest and hygienic surroundings. The removal of wards to the outskirts of the towns, and the erection of less permanent buildings which can be rebuilt and modernised every 40 or 50 years according to the advance of knowledge and changing conditions is surely a way of progress that demands consideration.

BRITISH MEDICAL ASSOCIATION.

ANNUAL MEETING IN MANCHESTER.

(Continued from p. 713.)

SECTION OF TUBERCULOSIS.

Apical and Subapical Tuberculosis.

Dr. D. P. **SUTHERLAND** (Manchester) presiding, Dr. **MAURICE FISHBERG** (New York) opened the discussion. Pathological anatomists and clinicians had, he said, long known that the number of people with tuberculous lesions in the lungs was much higher than recorded. The vast majority of tuberculous lesions were found in the apex of the lung and remained in that region. Nearly all cicatrised lesions which remained inactive and gave no trouble during life were in the apex. These lesions were often found clinically, and with the aid of X rays during periodical examinations of healthy persons, which were becoming the vogue in the United States. In patients with non-pulmonary tuberculous lesions, sent for chest examination, changes in resonance were almost invariably found at the apex of the lung, along with altered breath sounds and, perhaps, small adventitious signs; but such patients hardly ever offered significant pulmonary symptoms. In these cases, if death ensued because of the tuberculous infection, it was the result of acute pneumonic phthisis or more commonly miliary tuberculosis. Similar apical lesions were found among persons who suffered from frequent "colds"; they might spit blood and have tubercle bacilli in the sputum, but with or without therapeutic intervention they did well. It was such cases as these which were diagnosed as tuberculous by the ultra-cautious physicians, and supplied the material for any "cure" which happened to be introduced at the time. They also supplied the "early" and the "curable" cases considered suitable for sanatorium treatment. They were apparently the residua of childhood infection which had become obsolete. While 10 per cent. of civilised mankind died from active and progressive tuberculosis, it had been shown that only about 7 per cent. of the persons with apical lesions developed active tuberculosis or died from the disease.

Turning to subapical lesions, Dr. Fishberg remarked that valuable time might be lost in the diagnosis unless microscopic examinations of the sputum revealed tubercle bacilli, or unless X rays disclosed a soft clouded patch isolated in the midst of apparently healthy lung tissue just below the clavicle, often towards the axillary portion of the lung. The nature of the patch was broncho-pneumonic, of the type seen in primary tuberculosis in children or in tuberculous pneumonia in adults. Over 60 per cent. of subapical lesions manifested themselves in persons under 25 years, as against 30 per cent. of apical lesions. Over 35 years the percentages were 11 and 32 respectively. Under 25, unless a good radiogram was taken, or the sputum found positive, the case was missed. He stressed the importance of X ray examinations; in the United States every tuberculosis doctor had an X ray plant in his surgery right at hand. Early cavities were not as a rule revealed by physical signs, it needed X rays to disclose them. The differentiation of apical from subapical lesions was of immense therapeutic importance. At Bedford Hills Sanatorium, of the patients with subclavicular lesions, 66·4 per cent. had a positive sputum against only 15 per cent. with apical lesions. Strict isolation, the backbone of tuberculosis prevention, was not indicated in 85 per cent. of apical cases, which rendered prolonged and costly institutional treatment unnecessary.

Sir **Humphry Rolleston** (Cambridge) agreed that tubercle did not begin at the apex; but the term "apex" was often employed when speaking of conditions in the upper lobe. It was an interesting question whether the infraclavicular site was due to exogenous reinfection in a person who had lost his immunity from infantile infection, or an endogenous and metastatic reinfection from dormant foci, such as tuberculous glands, lying perhaps in close contact with the bronchi. Possibly both explanations were true in different cases.

Prof. **A. Ramsbottom** (Manchester) believed the majority of apical (in the strict sense) lesions originated in childhood, and were really blood-borne. Many of the apical lesions were of bovine origin, as opposed to the subapical which were of human origin. It was extremely difficult to decide whether a case was one of apical or subapical disease, and he confessed difficulty in finding a pulmonary lesion in some of the cases in which tuberculosis had been suspected from the general symptoms and the discovery of acid-fast bacilli. He considered the so-called "abortive" tuberculous case, with bacilli found for a short time, more of a pathological fact than a clinical entity.

Dr. **J. Watt** (Godalming) said some of his observations conflicted with those of Dr. Fishberg. He had compared two groups of cases, apical and subapical, similar in history and clinical course; in 72 per cent. of the apical and 81 per cent. of the infraclavicular tubercle bacilli had been found at some time or other. These figures were in contrast with Dr. Fishberg's 15 and 66·4 per cent.—a complete inversion for the apical. From the sanatorium at Godalming 58 per cent. of the apical cases and 48 per cent. of the infraclavicular were discharged with disease quiescent. Practically all the new work on apical and subapical tuberculosis was, he said, based on radiography, which was not yet infallible. Apical tuberculosis was not diagnosed in this country with anything like the frequency it was in America or Germany. His own figure of 72 per cent. showed that British sanatoriums did not needlessly keep cases. He believed that: (1) the initial lesion in the adult type of phthisis occurred in diminished frequency from the lung apex (sc. above the first rib) downward; (2) in general the nearer the tuberculous lesion lay to the apex the greater the chance that it would heal.

Dr. **W. Brockbank** (Manchester) said that pulmonary tuberculosis was almost unknown among workers in lime and plaster-of-Paris, and he described special investigations made in the North-East States of U.S.A. and in Canada, from which remarkable figures of immunity had been collected.

Dr. **Fishberg**, replying, said more of the apical cases would be found in private or consulting practice than in sanatoriums. In the United States they were using X rays to the utmost—they owed it to their patients. He thought the British statistics would assume a different character if every case was X rayed.

Sanocrysin Treatment.

Dr. **J. R. Gillespie** (Belfast) presided when Dr. **B. R. Clarke** (Belfast) read a paper on sanocrysin treatment in pulmonary tuberculosis. Sanocrysin in a pure state, he said, was not injurious to healthy mammals in doses of 0·1–0·15 g. per kilo of body-weight; tolerance was increased by graduated dosage. The kidneys were mainly responsible for its elimination which took place more slowly than was at first supposed. It was much more liable to damage a tuberculous organ than a healthy one. In afebrile patients it was safe to begin with 0·25 g., and to increase by the same amount in arithmetical progression until 0·75 g. had been reached, which dose might then be repeated four or five times. This sequence would usually be tolerated well by patients weighing from 8 to 10 st. Over 10 st. the final dose might be increased to 1·0 g. In very light or emaciated patients 0·5 g. should be the maximum. Interval between the early doses about a week, between the larger doses 10 to 14 days. In 16 per cent. of patients treatment had to be abandoned when less than 2·0 g. had been administered; some patients could not tolerate the drug, even in smaller doses. At the end of 1928 102 patients at the Forster Green Hospital had been discharged after sanocrysin treatment. Five cases given the original large doses all showed a loss of weight varying between 1¼ and 10½ lb., and developed some complication. In the remaining 97 treated by graduated doses, complications—the most serious being prolonged fever with a spread of the disease—occurred less frequently. Do not, he said, use sanocrysin unless there was a definite probability of obtaining better results with it than by conservative methods. Where sanocrysin was well tolerated, beneficial results followed in a high proportion of cases. The effect on fever cases which had not yielded to prolonged rest in bed was often very marked. For the positive sputum cases discharged from the hospital from July, 1925, to December, 1928, the after-histories were traced in the spring of 1929. Of the sanocrysin-treated, 80 per cent. of the moderate grade were alive against 63 per cent. of those not so treated; in the advanced grade, 58 per cent. of the sanocrysin-treated were alive, against 30 per cent. of the untreated. To sum up: sanocrysin was of value in two types, the early exudative cases with some resistance, and the predominantly fibroid type with symptoms and persistent tubercle bacilli in the sputum. In the exudative case he used sanocrysin as soon as possible; in the fibroid, not until sanatorium treatment had had a trial. Sanocrysin could in some cases be successfully combined with artificial pneumothorax. It was not a cure for pulmonary tuberculosis, but it was a valuable aid to treatment.

Dr. **F. R. G. Heaf** (Warwickshire) gave his experience of 120 positive pulmonary cases at the Warwickshire Sanatorium. He, too, had found the Danish initial doses too large. If loss of weight and rise of the sedimentation test occurred the interval between dryness of the throat. Early diagnosis was of the very greatest importance for the sake of treatment. Treatment should be primarily general, as the pulmonary lesion was the important one. Local treatment consisted in: (1) absolute voice rest; (2) galvano-cautery in selected cases. With voice rest even very large lesions might heal completely; it might need to be continued for as much as six months and the patients required constant encouragement. The cautery was valuable in carefully selected cases; it did not destroy the actual lesions, but acted as a counter-irritant. He had had little experience of direct sunlight treatment of the larynx, but found that the dose required very careful regulation. With artificial sunlight the treatment was lengthy, and he doubted whether a corresponding advantage was secured. In rare cases where the lung condition was inactive and the laryngeal progressive a tracheotomy might secure the complete rest of the larynx that was essential. In the later stages treatment should be symptomatic and directed to relief of cough and of pain. For the latter he relied on insufflations, and had been disappointed with nerve-blocking injections.

Sir StClair Thomson (London) recalled that one case in every three of phthisis suffered from a laryngeal complication, and estimated that 55,000 such sufferers existed to-day in England. Fortunately not only was phthisis becoming more rare, but the incidence of laryngeal tubercle was also declining. Formerly males had been more affected, but since the entry of women into the labour market the sex difference had largely disappeared. The more advanced the pulmonary disease the greater the incidence of laryngeal lesions. Further, the presence of a laryngeal complication was of great prognostic significance. Of the cases from a sanatorium without laryngeal tubercle two-thirds were alive ten years later; of those with laryngeal tubercle only one-third survived ten years. The difference was most pronounced among the early cases. When a laryngeal complication occurred during sanatorium life it was of grave significance. Of cases treated by silence alone the larynx was cured in one-third and improved in one-third. Among the rare cases selected for cauterisation 62 per cent. were cured. Of all sanatorium patients one-fourth were cured.

Mr. H. Morriston Davies (Ruthin) emphasised the importance of routine examination, even in cases of phthisis with no laryngeal symptoms. The presence of laryngeal tubercle was of material significance where operative treatment for the lung was under consideration. Healed laryngeal tubercle, if attended with much deformity, so that a good cough could not be produced, was a contra-indication for artificial pneumothorax. On the other hand, the presence of a laryngeal complication might determine one to do a pneumothorax operation, where without it one would not. Though of less significance where phrenic avulsion was contemplated the condition of the larynx needed even greater regard when a thoracoplasty was under consideration.

Sir James Dundas-Grant (London) pointed out that in cases of doubt a biopsy presented great advantages, especially where a thyrotomy might be contemplated. He relied on galvano-cautery for many cases of laryngeal tubercle, and thought pain especially was a pressing indication.

Mr. R. Scott Stevenson (London) had seen cases in which careful clinical and radiological examination failed to reveal any pulmonary tubercle, but where there was advanced laryngeal disease. Laryngoscopy was therefore important with any obscure chest condition.

Dr. S. Moritz (Manchester) emphasised the importance of using the galvano-cautery to effect deep punctures, to produce fibrosis, and not superficially. He referred to the difficulties presented by the simultaneous occurrence of syphilis and tubercle in the larynx.

Reviews and Notices of Books.

Stone in the Urinary Tract.

By H. P. Winsbury White, M.B., Ch.B. Edin., F.R.C.S., Assistant Urological Surgeon, St. Paul's Hospital. London: J. and A. Churchill. 1929. Pp. 344. 35*s.*

Close upon Mr. Swift Joly's recently published work on "Calculus" comes another treatise on the same disease by Mr. Winsbury White. The ground covered is the same, but the subject is treated differently. Whereas Mr. Swift Joly produced a monograph for the expert Mr. Winsbury White caters for the practitioner and for the general surgeon who deals occasionally with cases of stone. For this reason such matters as the ætiology of calculus formation are dealt with less fully in the book now under review, and more space is devoted to such practical points as lithiasis in pregnancy and in children. This addition will be appreciated by the expert as well as those for whom the book has been more particularly written. But as a matter of fact the book contains a vast amount of information interesting to all genito-urinary surgeons. The only criticisms we would offer are that (1) the arrangement of the subject matter is somewhat haphazard; when the book is used for reference it is difficult to find information without first consulting the index; (2) the important points in the treatment of stone do not receive enough emphasis at the expense of unessentials. The plates are excellent and are more numerous than is usual in a work published this side of the Atlantic. The bibliography at the end of the book is excellent. The author has searched out the literature of stone from the years 1910–28 so that those who require information not found in the text may know where to obtain it.

Orthopædic Surgery.

Second edition, revised. By Sir Robert Jones, Bart., K.B.E., C.B., F.R.C.S., F.A.C.S., and Robert W. Lovett, M.D., F.A.C.S. With the collaboration of Nathaniel Allison, M.D., F.A.C.S., Frank R. Ober, M.D., and Harry Platt, M.D., M.S., F.R.C.S. London: Humphrey Milford, Oxford University Press. 1929. Pp. 807. £2 12*s.* 6*d.*

In the interval of six years since we welcomed the first edition of this work the untimely death of Dr. R. W. Lovett, of Boston, has put an end to a fertile collaboration. Sir Robert Jones has wisely sought the help of two well-known orthopædic surgeons of Boston and of Mr. Harry Platt, of Manchester. The work has been brought thoroughly up to date, and the omissions which we called attention to in our former notice have been remedied. The excisions of obsolete matter have not balanced the additions, and the book is more than a hundred pages larger than it was. The number of figures has also been increased. Otherwise there is no great change in the book, nor is any revolution in treatment recorded. Scoliosis, which was a subject that the late Dr. Lovett made peculiarly his own, is dealt with at greater length than before, and details of new methods of applying plaster jackets are described. The sound, conservative opinions expressed in the first edition on arthroplasty of the knee, and the treatment of Pott's disease and scoliosis by bone-grafts or the methods associated with the name of Russell Hibbs, of New York, are repeated. The subject of backache or low back pain, as the Americans prefer to call it, is still discussed cautiously; the waves of enthusiastic surgery based on supposed subluxations, minor bone injuries, and abnormalities of development of the spine, seem to spend their energy before they reach these shores. The chapter on Volkmann's ischæmic paralysis is a valuable addition, and fills a gap which was left in the *first edition.* That on acute osteomyelitis is of notable value, and follows to a great extent the lines of the discussion in the Orthopædic Section of the Royal Society of Medicine last year. Fractures are dealt with at greater length in this edition, and this will especially enhance the value of the work to the practitioner who is not concerned with the more specialised branches of orthopædics.

PRINCIPLES AND PRACTICE OF MINOR SURGERY.

Sixth edition. By EDWARD MILTON FOOTE, A.M., M.D., Visiting Surgeon, St. Joseph's Hospital, &c.; and EDWARD MEAKIN LIVINGSTONE, B.Sc., M.D., Assistant Visiting Surgeon, Bellevue Hospital. London and New York: D. Appleton and Company. 1929. Pp. 787. 35*s*.

THIS work presents the principles and practice of minor surgery in all its branches in a logical, scientific, and readable manner. It is divided into three parts—minor surgical technique, the principles of diagnosis and treatment, and the practice of minor surgery. The author's interpretation of "minor" surgery is almost too liberal, for the volume includes consideration of every surgical procedure, outside the abdomen, with which the practitioner could legitimately be called on to deal. Details of the pathology and treatment of surgical conditions, as grave as rupture of the urethra, loose bodies in the knee-joint, or the operation of colostomy are given; yet there is no mention of appendicitis or of perforation of gastric or duodenal ulcers. *Apart from such curious regional* limitation the volume should prove invaluable to the practitioner, who is called on to deal with surgical cases and to the young surgeon. The teaching is quite modern and at the same time sound and practical. The majority of the illustrations are beautifully reproduced photographs.

ENDOCRINOLOGY AND ORGANOTHERAPY.

Diseases of the Thyroid Gland. Second edition. By A. E. HERTZLER, M.D., Surgeon to the Halstead Hospital, Kansas. London: Henry Kimpton. 1929. Pp. 286. 32*s*.

IN this new edition the result of a continuation of Dr. Hertzler's studies on the pathology of goitre and thyrotoxic conditions is presented. There are also included chapters dealing with the management of goitre patients and the technique of thyroid surgery, but the author's views on the pathology of these diseases are the chief point of interest. The most usually accepted classification of goitres divides them up into colloid goitres, adenomas without toxic symptoms, adenomas with toxic symptoms, and Graves's disease or true exophthalmic goitre. Dr. Hertzler holds that these groups do not represent separate diseases, but merely stages for the most part of one progressive disease. The same individual may run the gamut of the whole series. The colloid goitres are smooth in outline and the patient has no constitutional symptoms; their beginning depends on a uniform increase of colloid within the acini resulting in the homogeneous enlargement of the whole gland. This is the early stage. After a time new acini appear, adding their part to the increase in size of the gland; with their continued development the thyroid becomes irregular or bosselated. These are the glands which some authors call "adenomas." Hertzler believes that they are not truly "adenomatous," and he would reserve the term adenoma for the true benign tumours or fœtal adenomas. The latter develop from a single nodule and are isolated, encapsulated, and completely surrounded by the substance of normal thyroid on which they rest, but are independent of it in structure and growth. He suggests that the confusion in terminology is due to the failure to distinguish between the bosselations of an old colloid goitre and the fœtal adenomas. The clinical significance of these two varieties is entirely different. Hertzler holds further that the bosselated colloid goitres sooner or later become toxic, generally after about 10 years. The fœtal adenomas are not subject to the periodic progressions and recessions of the bosselated goitres and grow gradually. They may degenerate and form cysts or they may become malignant; sometimes they become mildly toxic, but this is comparatively rare. Finally, he would differentiate true Graves's disease from the toxic bosselated goitres. In true Graves's disease it is the proliferation of the epithelium of the original acini which is the characteristic feature, while in the toxic bosselated goitres the toxicity is due to the proliferation of acini developing in the interstitial cells.

These views require careful consideration, and their presentation in the present volume is clear and concise.

Organhormone und Organtherapie. By Prof. AUGUST BIER and others. Munich: J. F. Lehmanns. 1929. Pp. 91. M. 4.50.

THE principal thesis of this little book, which is made up of reprints from the *Münchener Medizinische Wochenschrift*, is that, since organs normally regenerate and give rise to substances which preserve the normal physiological balance, it should be possible to approach something like regeneration or at least re-established function by the administration of preparations of appropriate organs in cases of disturbed structure or function. This conception is, of course, being widely applied in many directions, but those followed in this book merit special attention, because a measure of success claimed by so distinguished an authority as Prof. Bier cannot be ignored. The book is divided into four parts. In the first Prof. Bier deals with the general principles of organotherapy and in particular with the work of his pupils, set out in the succeeding sections. The second part consists of a discussion of diseases of the liver and bile passages which have been treated by various extracts of liver, gall-bladder mucosa, and extrahepatic accessory glands. The substance chiefly used was choloton, and the authors frankly state that they are concerned with the clinical effectivity of the preparation and not with its mechanism of action. Cases of many varieties of liver and gall-bladder diseases have been treated with an improvement of symptoms (jaundice, pain, rigors, enlargement of liver, &c.) which impressed the observers. In the third part the treatment of tabes, progressive paralysis, and multiple sclerosis with a complex preparation of nervous tissue, vitamins, calcium, iron, and carbohydrate is described. This preparation is called Promonta, and is prepared in the cold on the principle of keeping the nerve substance unchanged. Treatment by the mouth with this substance combined with strychnine nitrate is said to have produced extraordinary symptomatic improvement. The last and shortest part deals with the treatment of Graves's disease by injection of animal blood. Sterile defibrinated ram's and calf's bloods were used, 5 c.cm. doses being injected intramuscularly at eight-day intervals. Anaphylaxis is obviated by using the different animals' bloods alternately, two to four injections being generally sufficient to produce a distinct improvement in symptoms. It is claimed by the authors that it is not merely the febrile reaction which determines the degree of improvement, but some more fundamentally important process. Time and large numbers of controlled cases only can decide on the reliability of these findings. The principles involved are vague, but the book is commendable in so far as it insists on a broader physiological outlook and gives many useful suggestions for further research.

Die Pathogenetischen Grundlagen der Thyreotoxicosetherapie. By JOHAN HOLST. Oslo: I. Kommisjon Hos Jacob Dybwad. 1928. Pp. 170.

THE introduction of iodine into the treatment of exophthalmic goitre has during the last few years given results which opened a new chapter in our knowledge of the diseases of the thyroid gland. It is quite clear that the theoretical basis for such a treatment is something totally different from that of the treatment of endemic goitre by iodine salts; for, whereas the latter is now well established as due to a deficiency of iodine, the former is associated rather with a flooding of the tissues with the active principles of the thyroid which are certainly in some way combined with iodine. Holst's work presents a definite advance in the direction of explaining this apparent paradox. He examines the problem by chemical, histological, and clinical methods. Administration of iodine (Plummer's method) in Graves's disease is followed by a rapid clinical improvement, fall in metabolic rate, and an increase in stored colloid in the gland itself. Analysis of the blood for iodine shows that this substance occurs in two main forms, one inorganic and alcohol soluble and the other organic, alcohol insoluble, and associated with protein. Both these fractions are much increased in thyrotoxic conditions. Treatment with iodine produces the effect of very largely increasing the inorganic fraction in the blood but of diminishing the organic to almost normal. Taking this in conjunction with the other observed effects of iodine Holst puts forward the view that the thyrotoxic condition is due to the flooding of the tissues with the active secretion of the thyroid, that this active secretion is identical with the organically combined iodine in the blood, and that the controlling factor is inorganic iodine in the blood. No information is given about the factor which gives rise to the so-called thyroid diarrhœa, for the high inorganic iodine in the blood cannot be the controlling factor normally. Throughout the book no mention is made of other glands which certainly have to do with the normal endocrine balance. Dr. Holst pays careful attention to the selection of the best period for operation after the preliminary iodine treatment, and to the fact that if this period is missed thyrotoxic symptoms again supervene as a result of hyperiodism. Emphasis is laid on the danger of intermittent treatment; once treatment with iodine is begun it should only be discontinued for operation. Clearly this treatment is not yet suitable for application in general practice. Its main value lies in so diminishing the thyrotoxic symptoms that [illegible]peration can be safely undertaken. Continued treat[illegible]nt after operation with small doses of iodine has in [illegible]lst's cases yielded good results.

The book is well worth studying because it is written by one who is both an endocrinologist and a surgeon. It is written in pleasant style, easy to follow, and the diagrams are excellent.

DIAGNOSTIC METHODS.

Diagnostic Methods and Interpretations in Internal Medicine. By SAMUEL A. LOEWENBERG, M.D., F.A.C.P., Assistant Professor of Clinical Medicine, Jefferson Medical College. Philadelphia: F. A. Davis Company. 1929. Pp. 1032.

THIS book has a wide scope, for the author's aim is to cover the field of diagnosis in medicine. The chapters devoted to the circulatory and respiratory systems are adequately dealt with and physical examination is lucidly explained; the examination of the abdominal viscera is not so well described, while the section on the endocrines suggests rather the small booklets thrust upon practitioners by commercial firms—for example, a differential table is given to distinguish between pineal and thymus hyper function. That such tables, which have no scientific foundation, should be incorporated and a method of such diagnostic value as the use of lipiodol omitted detracts greatly from the value of the book. The author likes differential tables, although the ones supplied are not of much diagnostic value. One table given is that of the differential points between "gall duct" (this term is new to us and its significance uncertain), "gastric ulcer," and "pyloric spasm." According to this table application of cold is supposed to ease the pain in gastric ulcer and to intensify it in pyloric spasm; this is not our experience. There are several omissions—for example, the reticulocytes are not mentioned in connexion with pernicious anæmia nor are Froin's syndrome and the protein content of the C.S.F. in the examination of the cerebro-spinal fluid. The photographs are numerous; many are good, others such as that showing the difficulties of percussion of the heart in the "extremely modest," are quite unnecessary. A photograph of the technique of entering a vein is given showing the operator equipped with a rubber glove, syringe in hand, piercing the dusky skin. The outcome of a close study of this work is that the task of writing a comprehensive book on diagnostic medicine is too heavy a task in modern times. If the author had confined himself to a monograph on the diagnosis of respiratory and circulatory diseases alone he would have achieved more success.

CLINICAL ELECTROCARDIOGRAMS.

Their Interpretation and Significance. By FREDERICK A. WILLIUS, B.S., M.D., M.S., The Mayo Clinic, Rochester, Minnesota. London and Philadelphia: W. B. Saunders Company. 1929. Pp. 219. 30s.

THIS book consists essentially of a large collection of electrocardiograms illustrating the various abnormalities which occur in different pathological conditions. Many of these records are interesting, and some are rare, as, for example, those given in the last chapter, which deals with the dying human heart. At least 50 per cent. of the records might have been omitted with advantage, for although good in themselves they are redundant; the remainder would have amply sufficed to illustrate all the points to which the author refers. Apart from a few tables dealing with mortality statistics, the text is of a most elementary character, and falls far below the standard of what might reasonably be expected in a book dealing with such a technical subject. Each chapter is followed by a comprehensive list of references, but these are unselected, and few of the papers to which they refer are even mentioned in the text.

JOURNALS.

JOURNAL OF INDUSTRIAL HYGIENE, September.—This issue is devoted to three papers, each concerned with some form of tuberculosis in industry. In the first B. S. Coleman points out how industry groups the adult community in a way which is convenient for fighting tuberculosis. By medical examinations on engagement, and supervision during employment, the tuberculous can be detected early and their fellows protected from contact infection, whilst industry can also provide for the convalescent that remunerative occupation which is so advantageous to cure.—In the second paper E. R. Hayhurst and his colleagues describe exposure to silica dust in a sandstone quarry in Ohio, where, notwithstanding the presence in the stone of some 95 per cent. silica, the death-rate from pulmonary tuberculosis is low. The evidence of this low mortality, based on statistics, is supported by the result of a careful medical examination of over 900 workmen. Illustrations are given which leave no doubt about the presence of a dust hazard at the quarry, and the puzzle is why the silica dust does not produce its usual effect. A clue may lie in the matrix or bond which holds the silica crystals together; it forms 3 to 8 per cent. of the mass and is composed of ankerite (carbonates of calcium, magnesium, and ferrous iron). At present, however, no other comparable instance can be quoted.—The last paper is by D. E. Cummings, who deals with the separation of particulate matter smaller than screen sizes into graded fractions. He describes a method by which dust particles can be accurately separated one from the other according to size. This method may be of value in preparing material for inhalation experiments. The article is one of a series of studies of experimental pneumonoconiosis.

THE LANCET.

LONDON: SATURDAY, OCTOBER 12, 1929.

THE FUTURE OF VACCINE THERAPY.

THE modern practice of vaccine therapy rests in effect less on any theory of immunity than on JENNER's success in protecting from subsequent infection with small-pox those who had been vaccinated with material from cow-pox. Indeed, the word vaccine introduced to describe this specific virus is now used in ampler connotation to cover any virus or bacterial body, even any foreign protein, which evokes a response when introduced into an animal body by inoculation. A vaccine has come to be almost synonymous with an antigen. It was PASTEUR who saw in JENNER's results the germ of a law of general validity—namely, that by causing an animal or inoculated person to undergo successfully a mild infection, protection is thereby obtained from a more severe infection of the same nature brought about naturally or artificially. The results of such active immunisation are essentially protective, and are specific for the virus inoculated. They are limited in applicability when a living virus is used, owing to the difficulty of finding one whose potency is naturally reduced, so that as a rule artificial ways of reducing the virulence must be adopted. Active immunisation by such attenuated viruses is used successfully in the treatment of rabies, and forms the foundation of the methods of producing immune sera in animals.

For use in man any virus, however attenuated, which is still able to propagate itself and thus increase in the site of inoculation or spread throughout the body is dangerous. Bacteria for vaccines in human therapy are therefore at least killed, usually by heat; the bacterial bodies may even be disintegrated chemically, as in detoxicated vaccines. Experiments with such bacterial vaccines, sometimes together with their soluble toxins, have been made in the treatment of human infections for a generation, but so far no therapeutic principles have been evolved that have received general acceptance. The choice of patients suitable for vaccine treatment, the methods of preparing the vaccinal material and of administering it, and the results that may reasonably be expected, even the successes claimed for vaccine therapy, are still debated. Certain facts have, however, accumulated. The body responds to any parenteral introduction of foreign protein by a reaction which may be so violent as to constitute shock, with profound effect on the nervous system, the circulation, and the heat-regulating mechanism. The reaction may be a local one, limited to the site of inoculation, and sometimes a focal one at the site of infection. On the other hand, there may be no apparent reaction. A consideration of experimental work on animals, and of the methods used in fighting animal diseases on a large scale, throws some light on the way vaccines work in therapeutics, if it be granted that the presence of antibodies in the blood gives an indication of the degree of immunity obtained, a proposition not yet established. In animals inoculation, especially intravenous inoculation, on three or four successive days produces a serum with high but evanescent content of antibodies. Vaccines at intervals of some weeks give sera with antibody of long duration. ALMROTH WRIGHT's opsonic work led to vaccine administration at intervals of several days to avoid a possible negative phase, and to the use of small doses of vaccinal material; his careful immunisation experiments were carried out with the control of the opsonic index. Since this method has lapsed into disuse, no real control is made in vaccine therapy applied to man, except that to avoid active and immediate harm to the patient. Under rather than overdosage is the rule. The tendency, too, is to use less often the bacteria cultivated from the individual, and to depend rather upon stock vaccines. Indeed the specificity of the vaccine employed may be disregarded, as in the use of typhoid stock vaccine for many conditions. Substances other than bacterial bodies may be used, and vaccine therapy then becomes frankly a non-specific protein therapy, the dosage and results being decided empirically. Many laboratory workers refuse to see in the use of vaccines anything more than a specific protection against a reinfection. Pathologists, however, working in close touch with clinicians and with the patient, seem to advocate vaccine treatment in a great number of infective processes. Meanwhile, the practitioner is in a quandary, swayed to and fro by his inadequately controlled clinical impressions, and yet hesitating to omit from his means of treatment anything that is likely to benefit his patient.

Theoretically it should be possible to divide cases of infective diseases into three groups. In the first the patient is doing well, the infecting forces are being dealt with adequately by the natural resistance, and no anxiety about the outcome need be felt. In the second group the infection is localised, but there is a state of unstable equilibrium between the resistance of the patient and the infection which at any time may be upset. Thirdly, there is the group in which the patient is doing badly and is being overwhelmed by the infection. The first group obviously needs no specific treatment in order to ensure recovery. In the third group a procedure bringing about further toxic effects is not to be contemplated lightly, and adding more poison may be actively harmful. It is probable that in the developments of the new chemotherapy there will be found a better means of treatment for such cases. It is only in the second group, where there is already some degree of resistance, that the possibility of stimulating that resistance and calling up further antibodies to the infecting germs by injecting vaccines should be considered. (In hydrophobia immunising treatment is begun after infection takes place, and completed before symptoms of the disease show themselves; but this is essentially prophylactic treatment, which is not now under discussion.) In this group of cases, where symptoms have already appeared but progress is delayed and resistance is inadequate, or is liable to break down at any time, medical vaccine therapy is largely used in practice, and the success of this method of treatment has been assessed differently by various observers. The scientific basis for it has not been demonstrated; the advocates of vaccines in treatment base their claims upon the evidence obtained by clinical judgment. Evidence in support from the experimental side is wanting, but this may well be due to the fact that investigators of the problems of immunity have been working on other lines. Even from time to time), by restricting to registered chemists the power to sell, by prohibiting sales to persons unknown or not vouched for, and by requiring entries of sales to be made in a Poisons Book. No doubt it was deemed right that a dangerous poison should be sold only by a qualified chemist, who would use his skill and judgment in warning the purchaser of the nature and quality of the drug supplied. In 1908, however, came the important relaxation which has enabled ironmongers, storekeepers, and other unqualified persons all over the country to sell arsenic freely. Section 2 of the Poisons and Pharmacy Act of 1908 declared that the restrictions of the 1868 Act were not to apply to poisonous substances containing arsenic, tobacco, or tobacco alkaloids sold for agricultural and horticultural purposes, provided that the seller was duly licensed by the local authority and that he observed the prescribed regulations. The obtaining of a licence seems to be a mere formality; the renewal of a licence is an easier process still. Regulations of 1909 require that sheep-dip and weed-killer must be kept in a separate drawer or closed receptacle, apart from other goods, and must not be sold at the same counter as food for human consumption. Regulations of 1920 (replacing earlier requirements) add that the poisonous substance must not be sold except in enclosed vessels or receptacles as received from the manufacturers, secured from leakage and labelled with the name and purpose of the substance, the word "Poison," and the seller's name and address. These rules are excellent so far as they go; but the law places no restriction on the storage or possession of arsenic in this form, nor is there any prohibition on sale to persons under age. Thus, as our legal contemporary observes, a chemist may not sell half an ounce of powdered arsenic to a youth under age who wants it for killing rats; but a corn-dealer may sell a gallon of liquid arsenic, or a pound of powdered arsenic made up into a packet and called "weed-killer," to any boy of 16 whom he knows, and who says he wants it for killing weeds in his father's garden. Further, it appears that even unlicensed persons are often found offering weed-killer for sale, either in ignorance of the law, or in the mistaken belief that any tradesman may sell these goods if they are supplied in the original package sent out by the manufacturer. The time seems ripe for reconsidering [illegible] other arsenical preparations are so indispensable [illegible] the garden, or on the farm, as to justify the exception made in their favour in 1908, and also whether the conditions of their supply and use are not, in any case, too free from control. It may be said that the public is weary of incessant restrictions, and that a would-be murderer will always manage, somehow, to equip himself for his nefarious purpose. The present laxness of the law, however, is in marked contrast with the retraints imposed by statutes in 1920 upon the possession of firearms and of dangerous drugs. It would be instructive to have statistics of the proportion of poisoning cases in which the obtaining of arsenic in the form of sheep-dip or weed-killer has "facilitated the commission of the crime."

THE BROAD TAPEWORM IN NORTH AMERICA.

THE past year has added considerably to what is known of the distribution and hygienic significance of the plerocercoid of *Diphyllobothrium latum* in the region of the great lakes of North America.[1] This stage is by no means restricted to the Michigan Peninsula. Infected fish have been reported by T. Vergeer[2] from Lakes Winnipeg, Manitoba, Nipigon, and Winnipegosis, from Lac la Biche, and from the Lesser Slave Lake; while H. E. Essex[3] has proved that *Cyclops brevispinosus*, *C. prasinus*, and *Diaptomus oregonensis* act locally as first larval hosts. It must be emphasised, however, that man is not the only definitive host of this cestode. There is, for example, a moderate infection of fish in the smaller Canadian lakes far from towns. In these parts, when Indians or white men while fishing for trout catch wall-eyes and great northern pike—fish constantly infected with the plerocercoids—such unwanted fish are fed raw to dogs, of which every man seems to have at least one, and some a pack; and the dogs are readily infected, as many as 19 parasites having been found in one animal.[4] Moreover, the broad tapeworm has been reported from the fox, *Vulpes fulvus*, and from the domestic cat. The grey wolf, lynx, mink, marten, racoon, and otter feed on fish, and Vergeer has readily infected the cinnamon bear, which in the spawning season has been known to scoop as many as 20 fish out of the water on to the bank before starting his meal. Man is thus but one of a number of definitive hosts used by *D. latum*, and that he cannot be the main one is shown by Vergeer's calculation[5] that the United States imports yearly from Canada upwards of 6,000,000 plerocercoids hidden in fish, while only about 200 cases of human infection have ever been reported from the United States. The risk to man can hardly be considered great enough to justify that ruining of an important industry, with great loss to concerns dependent on it, which would follow the exclusion of Canadian fish from the United States. Careful disposal of human sewage is evidently insufficient to prevent infection of fish, but man is readily and fully protected by the cooking of his fish food, and woman will lose her preponderant tendency to infection when the Jewess gives up her habit of tasting raw fish to test her skill in flavouring it.

PECTOSE AND ITS ALLIES.

THE class of substances, known as the pectins or pectic compounds, which occur in apples, pears, and other fruits as well as in such roots as turnips and carrots, form a valuable stand-by for the jam maker, and this circumstance has brought them within the purview of the Food Investigation Board. Mrs. M. H. Branfoot (née Carré), the author of a study[6] made on behalf of the Board, has herself contributed greatly to the clarifying of our knowledge of these obscure substances to which over 300 workers have directed their attention during the last 100 years. The essential difficulty of studying the pectins is that they are uncrystallisable, they form no well-defined compounds, they are difficult to purify, and chemically they seem to lead nowhere; and this in spite of the fact that such skilled workers as Regnault, Cross and Bevan, Winogradsky, and other well-known botanists and chemists have sought to clear up their relations. Braconnot seems to have been the first to realise (in 1825) that these bodies existed, but Frémy first described (in 1840) the parent substance, pectose, as an alcohol- and water-insoluble body associated with cellulose in the cell-walls of plants, but chemically very unlike cellulose. Later workers found pectose difficult to isolate in an unchanged state; acids and alkalis may dissolve it with production of pectin and pectic acid, but they also change it. Pectose, indeed, appears from the work of Fellenberg and Carré to be formed by the union of cellulose with pectin; acid hydrolysis resolves it again into its constituents. Ehrlich concluded that the natural pectin of plants may be conceived as a complex anhydro-arabinose-galactose-methoxy-tetra-galacturonic acid. The replacement of a variable number of methoxy-groups by cellulose may be supposed to confer insolubility on the complex, which would be hydrolysable to varying degrees by acids and alkalis, or by other hydrolysing agents such as the natural enzymes found in plants. Having regard to the difficulty of ensuring that one is dealing with a chemical individual, it is not surprising that such different empirical formulæ as $C_{42}H_{62}O_{37}$ and $C_{41}H_{60}O_{36}$ should be attributed to pectins from different sources. Mrs. Branfoot, after fully discussing the matter, concludes that pectin is a neutral methoxy-ester of pectic acid, represented by the formula $C_{41}H_{60}O_{36}$, and yielding 11·76 per cent. of methyl alcohol, whilst the basal molecule of fully de-methoxylated pectic acid is $C_{35}H_{50}O_{33}$, with a characteristic calcium content of 7·60 per cent. Intermediate *tri-, di-*, and *mono-methoxy* forms appear to exist, the jellying power, according to A. G. Norman, diminishing with the number of methoxy groups. Laboratory methods for the extraction and determination of pectic compounds from fruits and other vegetable products are described in this study, as well as commercial methods useful for the maker of jams and fruit jellies who wishes to stiffen his products, and so to avoid the troubles of the housewife whose jam will not set. The use of these products is specially called for when fruits deficient in pectose, like apricots, pineapple, and strawberries, are concerned. This practice is vigorously defended by the author who has made a particular study of the apple, following the changes of pectose into pectic acid, cellulose and methyl alcohol via pectin and the pectinic acids during ripening and the disappearance of these substances during rotting. The changes are made visible by staining sections with ruthenium red and other appropriate dyes. The monograph should appeal to the plant physiologist as well as to the fruit preserver and to the flax retter whose interest in pectic substances is confined to getting rid of them.

THERAPEUTICS FOR STUDENTS OF PHARMACY.

THE large number of words derived from the Greek *pharmakon* must be a puzzle to the lay mind; some refer to the doctor and his art, others to the pharmacist and his craft. But the line of pharmacy for the chemist, and pharmacology and therapeutics for the doctor, is one overstepped on both sides, and one which must be overstepped in training, at any rate, if a sound and liberal education is to be given. The strife which sometimes arises between doctor and chemist is not over what each learns, but what each practises. The professor of pharmacology and chemistry in the University of Washington has deliberately decided to write for the student pharmacist a text-book[1] on pharmaceutical therapeutics, including in his sub-title "with pharmacology." The book is eminently readable, running smoothly to the English ear; its general arrangement is therapeutic, according to the bodily system for which the drugs are most frequently applied. In his preface Prof. Lynn sets out a reasoned and, it seems to us, a reasonable defence of his action. There are, he tells us, a number of modern and very satisfactory books on pharmacology and toxicology for the medical student and practitioner, but no one has attempted to present, for the pharmacist, such a field in simple manner with general but without a practical therapeutic application. It is this gap in general therapeutic teaching which the writer wishes to fill, for the teaching of pharmacy is otherwise difficult. In describing each drug he considers the physiological actions most important in the treatment of disease and most significant in the diagnosis and treatment of poisoning. The principles of its therapeutic employment, which are closely associated with these actions, are given in outline without any attempt to describe the practical application. Therapeutic information is supplied for students of pharmacy and for their education rather than for their practice.

The danger of imparting general information to those who are not meant to apply it cannot have been overlooked by Prof. Lynn. The temptation to prescribe for such common ills as headache, constipation, and general debility is seldom resisted by the pharmaceutical chemist when pressed by a customer dissatisfied with his medical attendant or reluctant to pay a fee. If the pharmaceutical chemist is more interested in the purpose than in the technique of his profession he will study therapeutics with zeal and may find irksome the limitation of his life-work to the dispensing of remedies prescribed by others. It must be remembered, however, that the status and responsibilities of the chemist vary in different lands and in different epochs—for example, in France his profession stands exceptionally high. In Great Britain, too, there are signs of the expansion of opportunities in pharmaceutical chemistry, since the laboratories of the Pharmaceutical Society of Great Britain and Ireland have, in recent years, taken on important new duties. It is, however, mainly in one direction of therapeutics that the modern student of pharmacy is enlarging his experience; the many biological remedies now on the market are being standardised year by year according to methods which require special training, and an entirely different outlook will be demanded in future years if the increase in the number and popularity of these remedies is sustained. The curriculum of the student of pharmacy is likely to become almost as crowded as that of the student of medicine. Whether there is room for therapeutics, even in its most general sense, remains doubtful.

ENOUGH BUREAUCRACY AND NOT TOO MUCH.

A SPEAKER who last week addressed the Law Society's meeting at Bournemouth on the Rise of Bureaucracy chose as one of his supreme examples the departmental order which requires a cowman to wash his hands before milking. Bureaucracy is undoubtedly a grave disease of the body politic. Lord Hewart has forsaken his judicial detachment to attack it as the "new despotism"; Lord Wolmer has been exposing the defects of a nationalised post-office; the medical profession knows its own troubles in the departmental aspects of health insurance and in the Statutory Rules and Orders about the supply of dangerous drugs; many members of the public have their favourite instances of petty restrictions tolerable only in war-time, and of official tactlessness and stupidity. But are there many champions of the ancient liberties of England who are anxious to go to the stake on behalf of the right to supply dirty milk? The direct legislation of Parliament specifically enacted that Milk and Dairies Orders should—amongst other things—prescribe the precautions to be taken for protecting milk against infection or contamination and for preventing danger to health from the sale of infected, contaminated, or dirty milk. Accordingly, the Order of 1926 directs that any person engaging in the milking of cows or the distribution of milk shall keep his clothing and person in a cleanly condition, and that all cowkeepers shall see that the hands of the milker are thoroughly washed and dried before milking—with other precautions for the same purpose. It is true that this adds to the list of crimes which sufficed Elizabethan England, and that prosecutions for dirty hands may encourage lawyers to take nice points as to the exact meaning of "thoroughly washed." But if the country wants clean milk Parliament must require the *observance of elementary precautions, and the* Ministry of Agriculture must frame certain minimum standards. Parliament might, of course, legislate about such details itself instead of delegating its authority to a department; but Parliament is one of the worst possible bodies for legislative purposes; it is too big and too busy to attend to details. As for the loss of personal freedom which the Bournemouth speaker's instance involves, there are copious parallels in other fields of public health. Where an individual's act or neglect can imperil the health and safety of others he may have to surrender [illegible]g of his freedom. The notification of infectious disease, quarantine, vaccination, the cleansing of verminous persons, and the detention of the insane—all these have elements of interference and compulsion which are familiar in our Public Health Acts and in the even more stringent variants of local legislation. If, in a matter like milk-supply, the choice lies between the Bournemouth speaker's remedy of laissez-faire and the Ministry of Agriculture's Order, the public may swallow a small dose of bureaucracy with no ill-results.

[1] Pharmaceutical Therapeutics with Pharmacology, Posology, and Toxicology. By Eldin V. Lynn, Ph.D., Professor of Pharmacology and Chemistry, University of Washington, College of Pharmacy, Seattle. London: McGraw-Hill Publishing Co., Ltd. 1929. Pp. 431. 20s.

CONCERTED STUDY OF TUBERCULOUS INFECTION.

MANY of those who write in praise of team-work in research have never tried it; the research mind can only rarely be harnessed in a team. There are quick workers and slow, intuitive thinkers and plodders who add one to one with painstaking care, men whose gifts lie in manipulative skill, and those to whom technical laboratory work is an abhorrence. No doubt each individual can find work suitable to his needs, given the opportunities, but thrice blessed is he who can bring them together into an efficient and harmonious team. Such is seen in the record of a decade of work by a team of American investigators, organised by the Kenneth Dows Research Fund of Johns Hopkins University and Hospital, and published in a limited edition regardless of cost.[1] Each research is an entity in itself, but each bears upon the rest; all the papers have appeared from time to time in the *American Review of Tuberculosis* and an interval of seven years separates the first from the last. Throughout these studies the workers have had the advantage of the use of a culture of human tubercle bacilli isolated by Trudeau at Saranac in 1891. At the time of isolation it exhibited what might be called standard virulence for guinea-pigs, but after two or three years of incubator existence it underwent a noticeable diminution of virulence. This diminution proved, as time went on, not to be progressive to a vanishing-point, and the strain has retained a certain degree of infecting power for guinea-pigs, which has not changed during the last 20 years. Its newly acquired, though lessened, infectiveness has become a fixed and static property resisting all ordinary methods that have been aimed at changing it. The studies were designed primarily to elucidate two main problems in tuberculosis immunity—viz., the part played by the lymphatics in the localisation of tuberculous disease, especially in its chronic pulmonary form, and the mechanism by which this localisation favoured the development of the immunity processes. Early in the story comes Dr. W. S. Miller's study on the normal histological distribution of the lymphatics of the human lung, followed by his wax reconstruction models of a single tubercle in the lung, which enable the observer to visualise in three dimensions what he has hitherto only looked at on a plane surface. These models are probably unique. Then follow researches on the vascular supply and lymphatics of the lung of the guinea-pig and the rabbit by Dr. Miller, Dr. Krause, and Dr. H. S. Willis. Each research emphasises minute points of difference between these two animals which to the uninitiated might appear to be of no practical value whatever; but in subsequent papers the picture of lymphatic mechanism is built up to show that these differences are not devoid of meaning. Dr. Krause makes it clear that, although the tracheobronchial lymph nodes of the rabbit are small and unimportant, the intrapulmonary lymph tissue is large in amount and is supplied by blood from the pulmonary artery; consequently when intravenous infection with tubercle bacilli takes place, an intrapulmonary fixation of the bacilli by these lymph nodules follows. Here the anatomical distribution of the lymph nodules determines the focalisation of the disease. For the same reason the presence of large tracheo-bronchial glands in the guinea-pig determines the early localisation, in this case not in the lungs but in the hila. From this point Dr. Krause goes on to show how foreign particles passing through the lungs may be "embolised." If they are arrested there, they may remain in situ or they may be conveyed into tissue spaces and thence to the intrapulmonary lymphoid tissue as in the rabbit, or the hilum nodes as in the guinea-pig. Again, therefore, it is seen that the lymphatics are the determining points of focalisation. But not only do they focus infection, they control the rate of the dissemination of tubercle bacilli from the portal of entry onwards. In the normal guinea-pig dissemination takes place within three hours; in the immune pig, after subcutaneous reinfection with a virulent strain of bacilli, a great delay occurs in the transmission of tubercle bacilli from the point of entry to the customary places of localisation within the body takes place. The outstanding feature is not complete inhibition but retardation. This work on the lymphatics of these two animals, which are so frequently used in laboratory experimentation, is a valuable contribution to the pathology of tuberculosis. The importance of the lymphatics in the spread of this disease through the body has been recognised by all pathologists since the days of Sylvius, but the fact that variations in the lymphatic distribution in different animals might be responsible for so much variation in the pathological picture has hitherto not been clearly recognised. Its bearing upon the morbid anatomy of human tuberculosis is obvious. Finally, the work of Dr. Krause and Dr. Dorothy Peters suggests the existence of two factors in this mechanism—namely, tissue allergy and immunity. The allergic reaction is called into play by the tissue contact of immune animals with dissociated tuberculoprotein or with tubercle bacilli, and this is followed by an accelerated development of the characteristic nodular tubercle.

THE HEALTH OF SEAMEN.

THE Seamen's National Insurance Society is an organisation bound by its constitution to accept every seaman who applies for membership without regard to his age, state of his health, or any outside consideration. The membership is not of a specially selected class, and for this reason some figures set out at the annual meeting held in June last and now published in the report of progress for 1928 are of interest. Throughout the eight years ended in December, 1928, on the average 12 per cent. of their members received sickness benefit, but in both 1927 and 1928 the number represented 15 per cent. Detailed examination of the records does not indicate any exceptional causes for this increase in sickness. In 1927 influenza had a marked effect, but in 1928 the number of influenza cases was below the average. A more encouraging feature is the low incidence of tuberculosis and venereal disease. The membership of the Society as certified by the Ministry of Health has averaged a little under 60,000 during a period of 16 years, and the cases of tuberculosis have averaged little over 100 a year during this period. During the last eight years the deaths from tuberculosis have averaged one-seventh of 1 per cent. per annum. In the same period the known incidence of venereal disease has also been small. The Society's doctors have treated rather less than 150 cases a year, this number including members who have received medical benefit after being eligible for sickness benefit. The cases of venereal disease, as far as can be ascertained, represent one-fourth of 1 per cent. of the members of the Society. Sir Norman Hill, the chairman, in announcing these figures said that he believed them to present a very different picture from that drawn from other sources, but he knew of no grounds upon which their accuracy could be questioned. As regards tuberculosis there could be no possible reason for underestimate. Indeed, the Society was entitled to get substantial help from the local authorities in every proved case. He made no claim that the figures shown by the Society's records are generally applicable to all seamen, and put them forward only to suggest that those figures derived from other sources require closer investigation than appears to have been given them. Among the difficulties of assessing the sickness of seamen is, of course, the impossibility of obtaining reliable estimates of the total number of seamen. An individual may be described as a seaman on very slender grounds, especially in death certificates. The title is often used by those who find only seasonal employment at sea, and may be retained long after the man has left the sea to follow a permanent occupation on the shore.

A TREATMENT FOR EMPYEMA IN INFANCY.

EMPYEMA is still a very dangerous condition in infancy. In the United States, Spence[1] in 1920 found in a total of 201 cases that the mortality was 64 per cent. in the first year and 50 per cent. in the second. Cameron and Osman's[2] figures in this country three years later are in close agreement with Spence's, showing 66 per cent. mortality in the first year and 50 per cent. in the second. Of many methods advocated as means of reducing this high death-rate, one which has found favour on the continent is the use of optochin, a preparation of ethyl-hydrocupreine hydrochloride which has been shown to have an inhibiting effect on pneumococci in vitro. Woringer,[3] of Strasbourg, employs it as follows. As much pus as possible is aspirated from the chest, and a 5 per cent. solution of optochin is then injected into the pleural cavity in a dosage of 25 mg. per kg. of body-weight, the total dose not exceeding 500 mg. (10 c.cm.). This procedure is repeated three or four times at intervals of one to two days, and it is stated that the general condition of the child usually improves and the fever diminishes. If not, a second course of injections may be given and even a third or fourth. Some authorities, after aspirating the pus, wash out the pleural cavity with 100–200 c.cm. of a 0·5 per cent. solution, but Woringer is opposed to this on the grounds that it may cause shock and death. He has treated 30 children by his own method and 24 of them recovered completely. Five were operated on secondarily and successfully—and in the light of later experience he thinks unnecessarily—and there were six deaths. The mortality in the first year of life was 29 per cent. (7 cases) and in the second year 36 per cent. (11 cases). Eighteen children over the age of two were treated without a death. Optochin is said not to have any effect on the staphylococcus or streptococcus, and its action is purely local. After the first injections pneumococci are still present in the pus and stain by Gram's method, but it is stated that they will not grow in culture. Fever sometimes recurs as a result of pocketing and if this happens each pocket must be injected separately or the pneumococci, deeply embodied in fibrous deposits, may soon recover their virulence. Hence in Woringer's opinion no case should be pronounced cured until fever has been absent for several weeks. The pus disappears usually in two or three weeks, and radiography shows that even big masses of fibrinous deposit may be entirely resolved within five or six months. But since optochin has been found dangerous when injected intravenously in pneumonia it may well be asked whether there is any risk in introducing it in the pleural cavity. To this question Woringer replies that he has never seen any bad effects from its employment in the dosage recommended, and he even suggests that in some resistant cases the concentration should be cautiously increased from 25 to 50 mg. per kg. It is, of course, difficult to say how far any benefit from the treatment recommended is attributable to the repeated aspiration of pus. Woringer himself does not hold that the use of optochin will supersede operative measures, but he thinks it may be very useful, especially perhaps when it is desirable to defer operation owing to the coexistence of pneumonia and empyema.

EPIDEMIOLOGY IN ICELAND.

ACCORDING to a correspondent who has lately visited Iceland, and whose paper is concluded on p. 801 of this issue, "There are many striking differences in the behaviour of diseases in Iceland and other countries. A study of these differences might well throw important light on the ætiology of these diseases." As examples it may be noted that tuberculosis, which is declining in most civilised countries, is increasing in Iceland at rather an alarming rate. Poliomyelitis, on the other hand, according to the data supplied, seems to be clinically milder than when it is epidemic in similar environments such as rural Sweden—in spite of the fact that the high morbidity for such a small country suggests that the virus is spreading in an unsalted population. Islands have often been a fruitful field for biological research, as is well brought out by Russel Wallace in his classic "Island Life," because an insular environment permits the segregation, preservation, and evolution of fresh varieties of organisms, including man and microbe. In epidemiological research isolation is a tremendous asset, if not an essential requirement, since the factors involved are so numerous and complex that in areas where continual intermigration is going on between the hosts and parasites of neighbouring areas, the problems become almost hopeless of solution. This shows the importance of another noteworthy remark in our correspondent's article. "In such an isolated and sparsely populated country," he says, "an invading germ can be followed almost visually, as it passes from one lone homestead to another." From this it appears that Iceland is an ideal hunting ground for the epidemiologist. Of recent years, however, it has become more and more clear that epidemiological research, if it is to produce any useful results, must be prolonged over many years, and include extensive studies of the healthy as well as the afflicted, during inter-epidemic, as well as epidemic, periods. Ideally, at any rate, such research requires a team of medical ecologists which include among them clinicians, statisticians, bacteriologists, and (last but not least) a general biologist. Governments rarely care to subsidise such expensive and lengthy academic studies, which are unlikely to produce a visible or immediate return for their money. But should some great scientific organisation, such as the Rockefeller Foundation, be looking for promising material for epidemiological research, it almost seems as if Iceland, with its highly educated population, its learned medical men, and its natural geographical advantages, is the most promising field left in the world. The time is now or never; for as transport and intermigration become more rapid, frequent, and extensive every year, it will not be long before Iceland loses its unique character as a potential key to the mechanism of epidemics.

REGULATION OF THE DIABETIC DIET.

NOWADAYS a large proportion of patients take an interest in their own complaints and try to understand them as far as they can. Dissatisfied with the diagnosis of "an internal inflammation," they wish to know if their ulcers are gastric or duodenal and are often able to argue at length about the relative merits of medicinal treatment and a short-circuit. When this attitude leads to self-prescribing and treatment, pitfalls inevitably open before patient and doctor, but so long as it only means intelligent coöperation it may be valuable to both of them. Diabetes is perhaps the outstanding example in which such coöperation is important, and several manuals and sets of tables have been published for the use of patient and practitioner alike. The latest contribution is a "Diet Summary in Average Servings for Diabetics,"[1] by Dr. P. J. Cammidge. The basis, as the title implies, is a standard diet made up of helpings of food as they appear at the table. From this the diet for any particular patient is determined by a process of trial and error controlled by the usual examinations of blood and urine. The main articles of diet are grouped under the headings of protein, carbohydrate, fatty and miscellaneous foods. Average helpings are given in ounces and the relative amounts of protein, carbohydrate, and fat are set out in grammes and also in "rations." The "ration" is an arbitrary unit which has been found to facilitate working; 20·0 g. of protein = one protein ration (P.R.), 5·0 g. of fat = one fat ration (F.R.), and 4·0 g. of carbohydrate = one carbohydrate ration (C.R.). Thus the average serving of boiled cod is 3½ oz. containing 20·0 g. of protein and 0·2 g. of fat, and forms one protein ration. The tables offer a ready means of varying a diet within the limits laid down. A patient taking, say, six carbohydrate rations at a meal may have it in any one of the following forms, each one of which is regarded as an average helping: ¾ oz. sago, 1 oz. wheat flour or macaroni, 2 oz. chestnuts, 4 oz. potato, 5 oz. broad beans, or one average sized pear (5½ oz.), banana (7½ oz.), or apple (7½ oz.).

---

[1] Spence, J. L.: Amer. Jour. Dis. Child., 1920, xx., 545.

[2] Cameron, H. C., and Osman, A. A.: THE LANCET, 1923, i., 1097.

[3] Woringer, Pierre: Rev. Franç. de Péd., Feb., 1929

While this summary is apparently written in the first place for the use of medical men, it is one which could be handed with advantage to any intelligent patient if his diet had first been stabilised and if any experiments or alterations were made under supervision. The tables have been carefully compiled; they are practical and simple, and they should prove of real help in relieving the monotony of the ordinary diabetic diet. In the necessarily condensed introduction are several controversial statements. It will not be generally accepted that actual appeal to the balance is rarely required after a little practice. This may be, and often is, true in cases on diet only, but in insulin cases, particularly if large doses are required, a check should be made at least once a week even if daily weighing is not necessary to prevent errors creeping in. Discussion is also invited by the statement that if the patient is able to utilise less than 40 to 50 g. of carbohydrate daily, insulin will probably be required. Future editions would be made more useful by the addition of a general index of foods, arranged alphabetically for quick reference to the various groups. These criticisms apart, the brochure may be warmly recommended.

ASPIRATION DURING TONSILLECTOMY.

PULMONARY abscess is a very rare sequel of tonsillectomy but it is greatly dreaded, the more so because it follows a comparatively trivial operation. At one time it was taken for granted that inflammation in the lung was due to the anæsthetic, but its occurrence when local anæsthesia is used shows at any rate that this is not always so. As we pointed out a fortnight ago (Sept. 28th, p. 673) two theories at present hold the field: first, that the complication is a result of inhalation of infected material during the operation; the second, that it is caused by the lodgment in the pulmonary vessels of emboli from the site of operation. In this connexion it may be noted that pulmonary abscess is not uncommon after other operations, notably laparotomy. Our annotation described some experiments designed to test the inhalation theory, and it may be of interest to draw attention now to some other observations whose object was the same. Attempts have often been made to ascertain, by bronchoscopy and by indirect laryngoscopy, what is the quantity of material aspirated and what is its dispersion through the tracheobronchial tree during tonsillectomy under inhalation anæsthesia. Impressed by the inadequacy of these methods, R. V. May, T. W. Thoburn, and H. C. Rosenberger, of Cleveland,[1] have made an elaborate radiographic investigation of 25 patients, aged from 3 to 12 years, during and after the operation of dissecting out the tonsils under a general anæsthetic. The radiopaque material employed was iodised oil and olive oil in equal parts, of which 2 to 3 c.cm. was dropped slowly on to the posterior pharyngeal wall and immediately removed by swabbing. Radiograms of the anæsthetised patient were taken before and after the instillation of the oil, after the dissection of each tonsil, after removal of the adenoids, and six hours after operation. Secretions were removed on gauze sponges, except in two cases where a suction-pump was employed; these both showed aspiration into the bronchial tree. Of the results, 48 per cent., or almost half the cases, showed evidence of aspiration; in all but four cases the iodised oil had been eliminated by the time that the fifth radiogram was taken, after removal of the adenoids, and only one case showed any remaining after six hours. The authors justly claim that the use of skiagraphy in investigating the degree of aspiration during operation is much more informative than the methods previously employed. They conclude that aspiration may be diminished by the adoption of the extreme Trendelenburg position, by constant and thorough removal of all pharyngeal secretions, by a technique producing a minimum of mucous secretion and hæmorrhage, and by a degree of anæsthesia which preserves the irritability of the laryngeal and tracheal reflexes; further, that some degree of aspiration is unavoidable in all operations requiring an inhalation anæsthetic. The investigation does not, of course, decide the question whether pulmonary abscess is caused more often by embolism or by inhalation.

A POST-GRADUATE course for old students of the London Hospital will be held next week from Wednesday (Oct. 16th) until Saturday, and a provisional programme appears in our Medical Diary. Communications may be addressed to Mr. Hugh Cairns at the hospital.

THE Bradshaw lecture of the Royal College of Surgeons of England will be delivered at the College at 5 P.M. on Thursday, Nov. 14th, by Mr. R. P. Rowlands, and the subject will be a Review of the Surgery of the Gall-bladder and Bile-ducts. Students and others who are not Fellows or Members of the College may gain admission by presenting their visiting cards.

As we have already announced, the Harveian Oration of the Royal College of Physicians of London will be delivered at the College by Sir Wilmot Herringham on Friday next, Oct. 18th. Dr. J. A. Arkwright, F.R.S., will give the Bradshaw Lecture on Nov. 5th, his subject being the Virulence of the Micro-organism in Infective Disease. Dr. G. F. Still's FitzPatrick Lectures, on the History of Pædiatrics in the Seventeenth and Eighteenth Centuries, will follow on Nov. 7th and 12th; and the Lloyd Roberts Lecture will be given on Nov. 14th by the Rt. Hon. H. A. L. Fisher, F.R.S., whose subject is An Oxford Movement. The Harveian Oration will be at 4 P.M., and all the lectures at 5 P.M.

DONATIONS AND BEQUESTS.—Among other bequests the late Mr. J. D. Kay left £1000 to the Manchester Royal Infirmary.—Mrs. Polly Wharton, of Brights Cottage, Heckmondwike, left £1000 to the Heckmondwike Urban District Council upon trust to apply the income in defraying the expenses of sending to the seaside poor and sick children resident in the district, and £500 to the Heckmondwike Nursing Association.

XLVII.

THE MICROSCOPIC EXAMINATION OF FÆCES.

PART II.*—BACTERIA.

THE conditions of warmth, moisture, and pabulum obtaining in the intestinal tract are almost ideal for promoting the growth of micro-organisms, and a great variety of bacteria is to be found in the fæces. They are, however, really outside the body itself, and are to be regarded as essentially saprophytes, although under certain circumstances almost any of them may enter the body and become pathogenic. There are four great groups of bacteria normally appearing in the fæces; the coliform bacilli, the streptococci, the anaerobes, and the acidophile bacilli. The streptococci and acidophiles retain Gram's stain, as do most of the anaerobes, while the coliform bacilli are decolorised by Gram's method. A generation ago Combe advocated the simple staining of a smear of the fæces by Gram's method, and drew inferences from the proportion of bacteria which retained the violet coloration, to those which were decolorised and took up a counter-stain. Although this procedure has not led to results of practical application, a variation in the proportion of the bacteria of the four groups named does nevertheless occur, and one of the chief factors influencing this variation is the diet taken by the patient.

Influence of Diet.

The intestinal tract, which is sterile at birth, is soon found to contain bacteria. Normally about one-third of the dried fæces of healthy people on a mixed diet consists of bacteria. During the period of milk-feeding, the acidophile group predominates largely; but with the onset of mixed feeding, the bacterial distribution changes and soon resembles that of the adult, the coliform bacilli becoming the prominent group. The coliform and anaerobic bacilli preponderate with a high protein diet; whilst the *B. acidophilus* is increased on a high carbohydrate diet. Increase of streptococci follows an addition of glucose or cane sugar to the diet, and the numbers of viable streptococci are greater after a saline purge. Elimination of many putrefactive anaerobic bacilli and other proteolytic organisms, and reduction of the coliform bacilli, can be brought about by a lacto-vegetarian diet, with plenty of fruit and green vegetables, especially if lactose be added. Cultures of *B. acidophilus* may be given in milk to hasten the change of flora.

In addition to the normal inhabitants of the bowel, certain pathogenic organisms occur in *disease*, such as typhoid, dysentery, and tubercle bacilli. These will be dealt with before discussing the conditions under which the normal bacteria may cause disease.

The Typhoid-Paratyphoid Group.

In the typhoid-paratyphoid group of diseases the bacteria may appear in the stools from the first week onwards, and are recovered in one-third to one-half of the cases. Though other methods of diagnosis are more reliable—such as blood cultures during the first ten days, and the Widal reaction after that—culture of the stools is useful *as a control.* Bacteriological technique has much improved as the result of the experiences of the war; it is now agreed that before a positive finding is reported, the suspected organisms must not only conform to requirements in motility and fermentation of sugars, but also must be agglutinable by a standard serum. *Typhoid* and *paratyphoid* B bacilli, though less common than formerly, occur still in mild epidemics; *paratyphoid* A, an Eastern type, was more often met with during the war, brought by the troops coming from India. These diseases must be notified. The bacilli continue to be excreted in gushes for some time during convalescence, so that several negative reports at intervals should be obtained before the patient returns to ordinary life. Sometimes it happens that a patient, though apparently well, continues to pass enteric bacilli at intervals; he becomes a "carrier," and a source of unwitting infection of the rest of the community. Such a person should be isolated under medical supervision, and should be debarred from any occupation which entails the handling or distribution of foodstuffs. Unfortunately, in these cases, it is often difficult to get rid of the infection, which may continue for a long time in such places as the gall-bladder.

Dysentery Bacilli.

In cases of colitis due to infection with dysentery bacilli, the organisms can be recovered from the mucopus in a large majority of the cases in the acute stages; in chronic cases they are rarely found. Indeed it may well be that bacillary dysentery is always an acute infection, though sometimes quite a mild one; and that a chronic colitis following an attack of dysentery is kept up by non-specific bacteria as a secondary infection. The laboratory report should differentiate between dysentery bacilli of the *Shiga-Kruse* and of the *Flexner-Y* types. The former infection is a serious affair, since the *Shiga* bacillus has a toxic effect on the nervous system as well as on the intestine. Nowadays a good antitoxic serum is available. Infection with *Flexner* dysentery bacilli is milder; it may be troublesome, however, and even fatal in infants, or in elderly or debilitated patients. There are at least five members of this *Flexner-Y-Hiss* and *Russell* type, and no standard serum is available. Eliminative treatment, for example by sodium sulphate, is the best.

A number of bacilli, not true dysentery, but capable of producing colitis, are grouped together as *para-dysentery* bacilli, of which perhaps the best known are *Morgan's No. 1* bacillus in the summer diarrhœa of children, the *Sonne* bacillus associated with dysenteric symptoms, and the *Bacillus enteritidis* of *Gaertner* and *B. aertrycke* in food poisoning. The allied *B. suipestifer* (hog cholera bacillus) is important for animals and probably sometimes for man. There are also others whose claim to be regarded as pathogenic is not yet accepted. These will be dealt with later.

Tubercle Bacilli.

A report of *tubercle* bacilli can only rarely be unexpected. *Their presence in sufficient numbers to* be detected in a routine examination will occur only when there is gross clinical evidence of chronic bowel trouble. In children with phthisis, in whom all sputum is swallowed so that none is available for direct examination, pus containing tubercle bacilli may be *passed* in the motions. In suspected cases of intestinal tuberculosis, special methods of concentration with antiformin and inoculation of a guinea-pig may be required.

Cocci.

Staphylococci are not inhabitants of the intestine. When their presence is reported, a local infection of the lower bowel by abscess or fistula-in-ano should be sought for; otherwise it is a negligible contamination from the skin. *Streptococci*, on the other hand, form one of the important groups of the normal intestinal flora, and there are several varieties which may at *times be pathogenic.* The usual differentiation made is by their action on blood cells, so that they may be classified according as they produce a green pigment, or completely hæmolyse the blood corpuscles, or have no effect upon them. All three classes may be present in fæces. The non-hæmolytic one (*enterococcus*) is the commonest. It is usually not pathogenic, though it is reputed to be so at times, as a secondary infection following ulcerative states of the bowel. A variety of the enterococcus is believed by Bargen to be the causative organism in chronic ulcerative colitis; but this is not generally accepted by pathologists. The other two classes, green and hæmolytic streptococci, may also become pathogenic. If they invade the blood stream or tissues of the body, they may cause severe symptoms, but their presence in the fæces is not necessarily significant.

---

* Part I., on Cytology and Animal Parasites, appeared last week.

Other Micro-organisms.

The vibrio of *cholera* may be found in epidemics in the tropics, but does not occur in these islands. *B. pyocyaneus* (the bacillus of blue pus), *B. proteus* (a putrefactive bacillus often found in great numbers in watery offensive stools), *B. lactis aerogenes* (allied to *B. Friedlander*, the pneumobacillus), *B. fæcalis alkaligenes* and *B. pseudoasiaticus* are rather harmless findings in the fæces, though possibly they may become pathogenic at times in other situations.

The other groups of fæcal bacteria, anaerobic and acidophile, as well as the spirochætes and yeasts—except the ray fungus of actinomycosis—are not important so long as they remain in the lumen of the bowel; though it may be expected that as our knowledge of the biochemical products formed by these organisms from food-stuffs increases, there will be some evidence found on which to form conclusions about a possible "intestinal toxæmia."

While one-third of the dried weight of normal fæces consists of the bodies of dead bacteria, these bacteria in the lumen of the bowel are really, as already mentioned, outside the limits of the body proper, and are as unlikely to gain entrance to the body, unless there is a breach in the mucous membrane, as are skin organisms without some damage to the skin epithelium. Such a break in the mucous membrane of the bowel occurs in any abrasion or ulcer, and there is no doubt that a secondary infection of dysenteric and tuberculous ulcers takes place with the ordinary cocci and bacteria of the bowel. Even when the site of invasion is not obvious, we know that a septicæmia with colon bacilli may occur, and that these are often excreted by the kidney causing irritation and inflammation of the urinary tract. Just before death, too, the blood is often invaded by bowel organisms, which can be recovered in blood culture; being a terminal state only, this septicæmia of intestinal organisms is not important, as by the time it sets in the bowel wall has probably lost its normal protective power.

Criteria of Pathogenicity.

These conditions are, however, exceptional. What importance should be assigned to the bacteria which remain in the lumen of the bowel? It must be noted that the media used for culture of micro-organisms are artificial ones; though selective for some bacteria, they may even inhibit others. The amount of growth on culture media may bear little relation to the numbers of bacteria present in the fæces, or to their pathogenicity. Too much emphasis should not be laid on an apparent increase in numbers, such as an excess of streptococci; it has been shown above that great variations in numbers of streptococci occur with change of diet, and of the consistency of the stools. In pernicious anæmia and other conditions with subacidity of the gastric juice, there is a great numerical increase of the normal inhabitants of the bowel, *B. coli*, *streptococci* and especially the anaerobe *B. welchii*. But there is no evidence that these organisms differ qualitatively from those found in healthy persons, or that any individual type of organism is specifically related to pernicious anæmia. It is necessary, too, to avoid the fallacy of treating the patient for such conditions as the presence of coliform bacilli, which are atypical in having a delayed power of fermenting lactose. The usual *B. coli* rapidly produce acid and gas in lactose media, whilst most of the known *pathogenic* Gram-negative bacteria do not show this reaction with lactose in ordinary media. There is an intermediate group which ferments lactose after an interval of several days—some of them may even produce so much ammonia from peptone digestion that an acid reaction never appears—which are described alternatively as *para-dysentery* or *para-colon* bacilli. A few of these are of known pathogenicity, a few of known harmlessness; there is little evidence that the majority of them exert a harmful action on the animal body. The quality of delayed fermentation of lactose is not therefore significant. A further group of these colon bacilli is found to grow in the presence of normal active serum; some even hæmolyse red blood corpuscles. These serum-resistant and hæmolytic *B. coli* may be pathogenic, but we have no certain evidence on this point. The same is true of hæmolytic streptococci. Their ability to live in blood, digesting and destroying the red corpuscles, makes them, at any rate, potential parasites, and if they are found elsewhere in the alimentary tract—at the roots of teeth, in the crypts of tonsils, or in the discharge from nasal sinus infection, as well as in the fæces—their possible importance cannot be denied. But if the evidence we have of the pathogenicity of these groups of bacteria is doubtful, evidence of their relevance in a particular patient is usually unattainable; the presence of any sort of specific immune body in the patient cannot be demonstrated by serological tests.

Vaccines from Fæces.

The value in treatment of vaccines made from the fæces, though widely assumed in this country, is not proved by bacteriological criteria, and does not rest on the same scientific basis as, for example, typhoid preventive inoculation, or the treatment of diphtheria and tetanus with serum. Nor has it the support of solid clinical proof, such as that of the value of vaccination against small-pox. It rests mainly on clinical impressions, which, as time goes on, may need to be revised, or, at the least, defined and classified.

In view of the great difficulties which confront anyone attempting to assess the possible pathogenic significance of fæcal organisms, therefore, no clear indications can be found for their use in vaccine-therapy. Antibodies to them may be formed by a patient into whom they are injected, but we have no means of knowing whether these have any specific action or are likely to help the patient in resisting his disease. Although vaccines have a proved place in bringing about protection against subsequent infection, their rôle in treatment is by no means securely founded. Until further positive evidence is accumulated, therefore, we have no warrant for using any but those derived from organisms with known pathogenic action; the promiscuous use of vaccines from other fæcal organisms is unlikely to lead to useful results.

Physician, Ruthin Castle.

HOSPITALS AND MOTOR ACCIDENTS.—The British Hospitals Association is asking the Government to introduce a measure making it obligatory upon motorists to insure against third party risks, and empowering hospitals to recover from the insurance companies the cost of treating motor accident patients.

PUBLIC ASSISTANCE COMMITTEES AND HOSPITALS.—Under Section 1 of the Local Government Act of 1929 the London County Council will, on April 1st, 1930, take over the functions of the Metropolitan Asylums Board, as well as of the Boards of Guardians within its area. That area has been divided into ten sections, under a Public Assistance Authority of 48 members, 16 of whom will be coöpted from outside the Council, assisted by local committees. Hospitals are to be dealt with by a Central Public Health Committee, which is the Council's old Public Health Committee reconstituted. The county will be divided into five hospital areas, each of which will be coterminous with the boundaries of a group of boroughs. The scheme of rearrangements adopted by the Middlesex County Council provides that the Public Assistance Committee shall be composed of members of the Council only, coöption being confined to the local committees. Among the hospitals to be taken over by Middlesex are the North Middlesex (900 beds), the Hounslow Institution (800), Park Royal (778), Edmonton House Institution (700), and the West Middlesex (325).

OXIDATION-REDUCTION POTENTIAL.

A SUMMARY OF RECENT WORK.

BY N. F. MACLAGAN, B.Sc.
(From the Courtauld Institute of Biochemistry, Middlesex Hospital.)

IT has been known for many years that the animal body derives its energy from combustion—that is, oxidation—and the exact analysis of this process is therefore of fundamental importance in physiology. In dealing with any form of energy there are two factors to be considered, which are best illustrated in the case of heat energy. Everyone is familiar with the distinction between temperature, which may be termed the intensity factor, and the amount of heat, measured in calories, which is the capacity factor. The different nature of these two quantities is made clear by the experiment of dropping a red-hot needle into a bowl of hot water: the heat capacity of the needle is much less than that of the water, yet heat passes from the needle to the water. Chemical energy may be split into two factors in an exactly similar way, and in the special case of oxidation we may regard the oxidation-reduction potential as the intensity factor, exactly analogous to temperature, which is indeed frequently called heat potential. Oxidation-reduction potential therefore decides which one of two systems will oxidise the other, just as the temperature decides the direction in which heat will pass when two systems are connected; to complete the picture oxidising capacity as estimated by titration may be compared with the heat capacity (calories).

The conception is perhaps made clearer by taking the further example of neutralisation of a base by an acid, where the acidic power may be factored into titrable acidity (capacity) and hydrogen-ion concentration (intensity). This case is also of special interest on account of the similarity in the methods of measuring hydrogen-ion concentration and oxidation-reduction potential. In both cases the first approach was through the use of certain dyestuffs called indicators. Litmus is an acid base indicator which is red in acid and blue in alkaline solutions; moreover, it changes colour in a certain relatively narrow range of pH, so that in this range its colour is an index of the pH. Similarly, methylene-blue is blue in the oxidised and white in the reduced condition, and changes colour in a narrow range of oxidation-reduction potential; to revert to the first example, it may be compared to a thermometer which indicates heat potential over a limited range. Ehrlich[1] was the pioneer in this field, and he was able to demonstrate differences in the reducing power of various organs with respect to indophenol blue and alizarin blue. Much work of a similar character failed to produce any definite advance owing to the fact that the relationships between the different dyes were not understood; also no zero of oxidation-reduction potential had been established, so that quantitative deductions from the experiments were impossible.

In 1920 Gillespie[2] published the first observations upon the electrode potential of bacterial cultures, and it was this work which led W. M. Clark and his colleagues to their "Studies on Oxidation reduction,"[3] which have thrown such a flood of light upon the whole problem. With the aid of electrode measurements they have been able to arrange a large number of dyes in an orderly series on a definite scale of oxidation-reduction potential, and as a result of their work it is now possible to make a fair estimate of the oxidation-reduction potential by observing the colour of a suitable dye. In order to understand the relation between the electrode and the dye methods, it is necessary to consider in more detail the chemistry of oxidation.

The Conception of Electron Transfer.

The older chemists regarded oxidation as an addition of oxygen or a subtraction of hydrogen, and reduction as the reverse. But with the development of the ionic theory this view has given place to a more general one, which may be conveniently illustrated in the oxidation of ferrous to ferric chloride

$$2FeCl_2 + Cl_2 = 2FeCl_3.$$

It is known that both $FeCl_2$ and $FeCl_3$ exist in solution mainly in the ionised form, so that this reaction may be written

$$(2Cl^- +)\,Fe^{++} + Cl \rightleftharpoons Fe^{+++} + Cl^- (+2Cl^-).$$

Evidently the essential part of this reaction is the transference of an electron—the unit negative charge of electricity—from the ferrous ion to the chlorine atom, which is thereby converted to an ion; so that the chlorine may be regarded as merely taking up the electron liberated in the oxidation of ferrous to ferric ion, which is therefore represented thus:

$$Fe^{++} \rightarrow Fe^{+++} + e.$$

This idea is of very wide application, and in general oxidation and reduction are associated with a loss and gain of electrons respectively

$$ox + e^{+} \rightleftharpoons red^{-} \quad \text{(Equation I.).}$$

On comparing this equation with that for the neutralisation of a base by an acid

$$H^{+} + OH^{-} \rightleftharpoons H_2O$$

it is evident that the reducing intensity of a solution is determined by the "concentration of free electrons" in the same way that the acidic intensity is determined by concentration of hydrogen ions. Apparently also a plate of noble metal may be regarded as an "electron electrode" in the same sense that a film of adsorbed hydrogen is regarded as a hydrogen electrode. Thus, when an electrode of plain gold or platinum is immersed in a solution, the potential set up is a measure of the reducing intensity of the solution and is called the oxidation-reduction potential E_h.

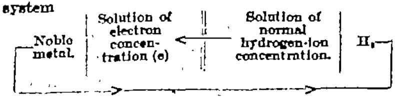
It should be noted that this treatment is purely formal, and that no objective reality is to be attached to such terms as "concentration of free electrons." There is, in fact, no evidence of the existence of free electrons in aqueous solution, and a difference in the mode of action of the hydrogen and oxidation-reduction electrodes is postulated which is probably fictitious; moreover, for the sake of simplicity, concentration is here substituted throughout for activity. The equations obtained by more rigid methods are, however, identical with those derived on the above hypothesis which has the advantage of presenting a clearer mental picture of the terms involved.

The oxidation-reduction potential is a single electrode potential whose absolute value cannot be determined, since a second single electrode must be coupled with the first before a measurement can be made. It is the practice to refer all such measurements to the normal hydrogen electrode, to which a potential of zero is arbitrarily assigned—that is, when an oxidation-reduction electrode is coupled with a normal hydrogen electrode the potential developed is attributed entirely to the former. This convention is expressed in the following equation:

$$E_h = -\frac{RT}{NF}\log(e) \text{ volts (Equation II.)}$$

when R = gas constant; T = absolute temperature; N = number of electrons transferred; F = the faraday.

This equation represents the potential difference of the system



Noble metal.
Solution of electron concentration (e)
Solution of normal hydrogen-ion concentration.
H_2

the potential at the liquid junction being neglected. It is further agreed that E_h be taken as positive when the current tends to flow as in the diagram. E_h is then an index of tendency to oxidise. Solutions having a positive E_h will oxidise, those having a negative E_h will reduce the normal hydrogen electrode. Also any solution will tend to oxidise one having a smaller, and tend to reduce one having a greater E_h than itself.

Reversible Reactions.

It is important to recognise that this treatment applies only to a perfectly reversible process, and herein lies the difficulty of applying it to living systems, whose processes are not in general reversible. However, we must consider together with this restriction the probability that many biological oxidations which are apparently irreversible proceed by a number of stages, some of which are truly reversible.

A further limitation of the theory outlined above arises when the reaction velocity is considered. The oxidation-reduction potential certainly decides in which direction the reversible reaction will proceed but does not say at what rate; this rate may be infinitesimally small, in which case the reaction does not proceed at all. The rate is, of course, frequently greatly affected by the oxidative catalysts, whose influence must therefore always be an essential factor in the problem.

The physical meaning of equation II. is revealed by application of the law of mass action of equation I.

$$(e) = K\,\frac{(\text{red}^-)}{(\text{ox})}$$

Substituting in II.

$$E_h = \frac{RT}{F}\log K - \frac{RT}{F}\log\frac{(\text{red}^-)}{(\text{ox})}$$

$$= E_0 - \frac{RT}{F}\log\frac{(\text{red}^-)}{(\text{ox})} \text{ (Peter's equation).}$$

E_0 is a constant for any one reaction and is obviously equal to E_h when $(\text{red}^-) = (\text{ox})$—i.e., at half oxidation.

It will have been noticed that the reductant in the above equations is an anion. This is a special case, but it is obvious that one or both of the reactants must exist in the ionised condition when an electron transfer is regarded as the essential process—e.g.,

$$\text{ox} + e \rightleftharpoons \text{red}^-$$
$$\text{ox}^+ + e \rightleftharpoons \text{red}$$
$$\text{ox}^+ + 2e \rightleftharpoons \text{red}^-$$

Thus the hydrogen-ion concentration may also affect the system as shown by the following equation:

$$H^+ + \text{red}^- \rightleftharpoons \text{Hred}.$$

In such a case it is usually only possible to measure the total reductant

$$S_r = \text{Hred} + \text{red}^-$$

and the relation of this to the active reductant red^- evidently depends upon pH. The following equation applies:

$$E_h = E'_0 - \frac{RT}{F}\log\frac{Sr}{So} \text{ (Equation III.)}$$

where E'_0 is a function of the pH.

It is interesting to note that this relationship between E_h and pH is a mutual one, so that changes in the oxidation-reduction system will affect the pH; the two equilibria are closely interconnected.

Equation III. is the basis of the indicator method of estimating oxidation-reduction potentials, which has been so thoroughly worked out by Clark and his colleagues. They have constructed E_h–pH percentage oxidation curves for a large number of indicators whose reduced and oxidised forms are differently coloured. If one of these dyes be added to a solution of known pH, in an amount so small as not appreciably to affect the existing equilibrium, the colour becomes an index of the oxidation-reduction potential. By choosing suitable indicators which change colour in the E_h (and pH) range under investigation a fair accuracy is obtainable.

Biological Applications.

The oxidation-reduction equilibrium is at least as important in the body as the acid-base equilibrium. It may therefore appear at first sight somewhat remarkable that the quantitative measurement of oxidising intensity—E_h—should have lagged so far behind that of acidic intensity—pH—in biology, but this is only the result of pushing the analogy too far. Neutralisation is evidently a unique process in aqueous solutions as it is a single reversible reaction in which the water takes part:—

$$H^+ + OH^- \rightleftharpoons H_2O.$$

On the other hand, the terms oxidation and reduction include a vast number of reactions, many of them irreversible, whose only common property is an interchange of electrons, and is thus not specifically related to the solvent. In addition, the interpretation of measurements is made difficult by our ignorance of the exact chemical mechanism of the simplest biological oxidation. The probable participation of reversible processes in these apparently irreversible oxidations has already been mentioned, but it would appear that few such processes have yet been found which are susceptible to electrode measurement.

It has been mentioned above that the earlier researches with indicators commenced by Ehrlich in 1885 did not produce any very definite results; the review of Needham and Needham[11] contains an excellent account of these researches. Clark and his collaborators have now removed many of the practical and theoretical difficulties, with the result that since 1920 there has been published much important work of which only the outstanding features can here be noticed.

The Reduction Potential of Bacteria.

The reduction potential of bacteria was first studied electrometrically by Gillespie,[9] who showed that anaerobic cultures developed increasingly negative potentials, the actual values obtained being very different in the few cases investigated. This was confirmed by Cohen, Cannan, and Clark,[4] who obtained similar results with cell suspension and who have also made some very interesting preliminary observations on the influence of glutathione on the development of these potentials. They conclude that the aerobic tissue cell or bacterial culture is roughly poised between +0·1 and 0·2 volts E_h. The system is not, however, in equilibrium with the atmospheric oxygen, which serves merely to oxidise the reducing substances elaborated in the cells at such a rate that the E_h is maintained within these limits. Under anaerobic conditions this controlling factor is removed and the E_h gradually falls, producing death of the cells (except in anaerobic organisms).

Evidently the classification of bacteria into aerobes and anaerobes has some reference to E_h. Quastel and Stephenson[12] concluded from their work on *B. sporogenes* that the behaviour of obligatory anaerobes is best explained on the assumption that they cannot grow above a certain potential. Similar results were obtained by Fildes,[8] who showed that the germination of spores of *B. tetani* failed to occur in media whose E_h was greater than +0·01 volts. Moreover, he explains the fact that this strain will not grow when injected into the guinea-pig by the incompatible E_h of the subcutaneous tissue fluid.

Intracellular Measurements.—In addition to these extracellular investigations, direct measurements of the intracellular E_h have been made by a method first introduced by Needham and Needham[11] which consists of making micro injections of suitable indicators into the living cell. This method has also been used by Brooks[1] Cohen, Chambers, and Reznikoff[5]

Rapkine and Würmser[13] Chambers, Pollack, and Cohen[3] and in view of the difficult technique it is perhaps not surprising that absolute agreement has not yet been reached. The aerobic potentials are mostly of the same order as those recorded by Cohen, Cannan, and Clark for bacteria and cell suspensions, but while the Needhams maintained that the E_h of the *amoeba proteus* was unaffected by anaerobiosis, the later workers found a fall of potential under these conditions. It has been emphasised by Cohen, Chambers, and Reznikoff that three factors are concerned in the interpretation of the results of these experiments—the intensity, capacity, and rate factors,—and it is no doubt the difficulty of allowing for the last two which is responsible for the existing uncertainty.

In this connexion, Cannan's work on *mercuralis perennis* is of great interest[2]; this plant contains a pigment, hermidin, which is in fact a reversible oxidation-reduction indicator, so that the E_h can be found in this case under perfectly normal conditions. It proved to be about —0·1 volts.

Oxidative Enzymes.

It was shown by Dixon and Quastel[6] that the system consisting of a mixture of reduced and oxidised glutathione was an anomalous one, for the potential proved to be independent of the concentration of the oxidised form. This implies that the change from reduced to oxidised glutathione is an irreversible one and therefore cannot be studied in this way, but the production of a stable potential is still of great interest, especially as it is not certain that glutathione acts through the change from reduced to oxidised forms. The cystine-cysteine system is in the same class, and the researches of Michaelis[10] and co-workers on the electrode potential of cysteine is yielding valuable information about its metallic complexes. Compounds of this type have been shown by Warburg[14] to be intimately concerned with tissue oxidation, and while the mechanism responsible for these potentials is still uncertain it is considered probable by Michaelis and Flexner[10] that the sulphydril group is the principal poising agent in the cells.

In conclusion, it may be emphasised that accurate work on oxidation-reduction potential in biology has only been going on for about nine years, and that much of the time has been taken up with essential chemical preliminaries. The importance of the subject cannot be doubted, and it is reasonable to expect considerable advances in the near future.

SALE OF ST. BARTHOLOMEW'S HOSPITAL LANDS.—The Charity Commissioners have sanctioned the sale of 310 acres of building land at Stanmore belonging to St. Bartholomew's Hospital. The price paid for 240 acres of Kenton Lodge Farm, Stanmore, is £62,730. An option, exercisable within 12 months, has been given on the purchase, for £21,137, of a further 65 acres adjoining.

ST. MARY'S HOSPITAL POST-GRADUATE COURSE.

THE post-graduate course held at St. Mary's Hospital during the first week-end of the winter session has become deservedly popular among practitioners. The attendance this year was as large as usual, in spite of the fact that other teaching hospitals are adopting the excellent plan of providing at this season of the year a short concentrated course. We publish on p. 751 of this issue one of the lectures delivered at St. Mary's, and abstracts of two of the other lectures are given below. We hope in the future to give further space to addresses delivered at St. Mary's and at other hospitals in London during this month. Mr. T. G. Stevens chose for his subject

Retention of Urine in Women.

Retention of urine, he said, though not a common trouble in women, might be a serious one if imperfectly treated. Its causes ranged from hysteria to a retroverted gravid uterus. Retention of urine might complicate or follow labour, and might also follow operations, especially those for prolapse. It might also be the result of the pressure of tumours and other lesions. Hysteria in young girls might lead to retention of urine, from simple functional failure of micturition. Before making the diagnosis, hæmatocolpos, of which retention may be the first symptom, must be excluded, and also rare pelvic tumours. Hysterical stigmata should be looked for. All ordinary efforts to promote micturition should be tried before a catheter is passed, but this operation should not be postponed longer than 24 hours at the utmost. Usually all simple methods fail, and one passage of the catheter may cure. No doubt the discomfort of the passage has some effect, but suggestion plays a greater part. According to Mr. Stevens, retroverted gravid uterus is the commonest cause of retention of urine in women, but is frequently overlooked. The history is misleading, some women stating that they are "always passing water," when they mean that they are always wet from the dribbling overflow of a fully distended bladder. A fatal mistake is to treat such a case as one of frequency of micturition without a careful examination. *Any* micturition trouble in the presence of a large abdominal tumour ought to raise the suspicion of a distended bladder, and demands the passage of a catheter. The danger of retention with overflow is that of infection of the distended and atonic bladder. In such a bladder the results of infection are far worse than in common cystitis with an empty bladder. Sloughing of the mucous membrane may occur, and infection may travel up the periureteral lymphatics to the kidneys, with the production of multiple abscesses (surgical kidney), septicæmia, and uræmia. In common cystitis with an empty bladder ascending infection seldom occurs. In the absence of overflow the passage of a catheter prevents all these dire results, and once the bladder is empty a retroverted gravid uterus can easily be felt filling the pelvis. If this can be replaced easily with the fingers, as it often can, the cure is at once complete. If, however, manipulation fails, a cure can still be obtained by keeping the patient in bed, lying in the semiprone position, and by passing a catheter to empty the bladder every eight hours. If this method is adopted the uterus usually replaces itself in about three days. A large ring pessary in the vagina often assists the replacement, but will have no effect if the patient is walking about. It is never necessary to induce abortion to cure these cases, but spontaneous abortion sometimes occurs, especially if efforts at finger replacement are too vigorous. Mr. Stevens pointed out that while retention during labour may be caused by the pressure of the fœtal head on the neck of the bladder, after labour inability to micturate is solely the result of fatigue and the stretching of the abdominal muscles. The patient is unable to make even the small straining effort necessary for micturition in women; it is interesting to note that few women realise that any effort at all is involved. After prolapse operations retention may also be due to the fact that the slightest strain causes pain in the new perineum, from stretching of sutured tissues; hence the patient at once inhibits the effort and micturition may fail. If with the first strain the act starts, the patient usually has no further trouble. Drugs, such as hexamine or boric acid, which irritate the bladder, will sometimes assist the act, but usually in post-operative cases a catheter has to be passed very gently every eight hours for several days. The only common tumours which compress or stretch the urethra and neck of the bladder are cervical fibroids, but occasionally fibroids in the body of the uterus may have the same effect, especially if the uterus is retroverted. It is rather a stretching of the urethra than actual compression which leads to retention in these cases, in which the catheter always has to be passed a long distance, sometimes as much as five inches, before the urine will flow. Mistakes may arise if the catheter is not passed sufficiently far, for no urine will be obtained, and the distended bladder may be taken for an ovarian cyst. Ovarian tumours rarely cause retention, but when they do it is because they are incarcerated in the pelvis. Incarceration may be brought about by adhesions in Douglas's pouch; but certain ovarian tumours have the broad ligament stretched over them, and thus tend to lever up the uterus out of the pelvis and to press it against the neck of the bladder and pubes. A pelvic hæmatocele, if large enough, may also press the uterus against the neck of the bladder, and so may widespread pelvic suppuration. Once any pelvic mass has caused retention an abdominal operation for its removal is imperative, the bladder being kept empty by catheter until the operation can be done.

Diabetes.

Dr. C. M. Wilson said that sepsis was like a magnifying mirror that stood between the observer and the diabetic, and until it was removed it was impossible to obtain an undistorted view of the diabetic's condition. He brought forward examples of recovery of carbohydrate tolerance following removal of sepsis. A woman who required 50 units of insulin daily was able to achieve the same results with 8 units a few weeks later after the removal of septic tonsils and septic teeth. A musician, whose unstable temperament made treatment by both dieting and by insulin equally unsatisfactory, had 10 per cent. sugar in his urine. After drainage of a septic bladder he became sugar free, without any change in the rest of the treatment. Dr. Wilson pointed out that the removal of tonsils since the introduction of insulin was a reasonably safe procedure if an adequate amount of carbohydrate was given and utilised, that the consumption of fat in the days previous to the operation was drastically curtailed, and that the minimum of anæsthetic was given. He was, however, far from advocating that surgical procedure should be lightly embarked upon. The evidence of sepsis must be adequate. When this was absent, or had been removed, it was necessary to decide whether the treatment should be confined to dieting, or whether insulin should be administered. Earlier he had been reluctant on grounds of expediency to use insulin except in those patients where its use could not be avoided, but at the present time he was using it in a much larger proportion of cases. The general condition of the patient was often much more satisfactory with insulin, and its use enabled him to cut down the amount of fat that was necessary. He aimed at giving a diet to an adult containing 80 to 100 g. carbohydrate, 1 g. of protein for each kg. of the patient's weight, and sufficient fat to maintain the weight rather below normal without acidosis. The limitation of protein was frequently neglected, since it was overlooked that sugar could be formed from protein, and that the proportion of protein given was an important factor in the production of acidosis.
